APPROXIMATING SEMIDEFINITE PACKING PROGRAMS*

G. IYENGAR†, D. J. PHILLIPS‡, AND C. STEIN§

Abstract. In this paper we define semidefinite packing programs and describe an algorithm to approximately solve these problems. Semidefinite packing programs arise in many applications such as semidefinite programming relaxations for combinatorial optimization problems, sparse principal component analysis, and sparse variance unfolding techniques for dimension reduction. Our algorithm exploits the structural similarity between semidefinite packing programs and linear packing programs.

Key words. semidefinite programming, combinatorial optimization, approximation algorithms, primal-dual methods, nonsmooth optimization

1. Introduction. In this paper we are concerned with solving semidefinite programs (SDPs) of the form

\[
\begin{align*}
\max \quad & \langle C, X \rangle \\
\text{subject to} \quad & g_i(X) \leq b_i, \quad i = 1, \ldots, m, \\
& X \succeq 0,
\end{align*}
\]

where \( C \in \mathbb{R}^{n \times n} \) is a symmetric, positive semidefinite matrix, \( X \in \mathbb{R}^{n \times n} \) is the decision variable, and \( g_i(X) \) are packing functions. The class of packing functions is formally defined in Definition 1 and includes as special cases \( g(X) = \langle A, X \rangle \), where \( A \succeq 0 \), \( g(X) = (\sum_{i=1}^k (\langle A_i, X \rangle)^2)^{\frac{1}{2}} \), and \( g(X) = \sum_{i,j=1}^n |X_{ij}| \). The Frobenius inner product \( \langle A, B \rangle \) between symmetric matrices \( A \) and \( B \) is defined as

\[
\langle A, B \rangle = \text{Tr}(A^T B) = \sum_{i=1}^n \sum_{j=1}^n a_{ij} b_{ij}.
\]

The constraint \( X \succeq 0 \) indicates that the matrix \( X \) is symmetric and positive semidefinite; i.e., \( X \) is symmetric and has nonnegative eigenvalues, or, equivalently, \( v^T X v \geq 0 \) for all \( v \in \mathbb{R}^n \). We refer to semidefinite optimization problems of the form (1) as packing SDPs. Packing SDPs arise naturally in many applications, including semidefinite programming relaxations for combinatorial optimization problems, sparse principal component analysis, and sparse variance unfolding techniques for dimension reduction. See section 2.1 for a detailed discussion of optimization problems that can be

reformulated as packing SDPs. The term packing SDP is derived from the fact that (1) is a packing problem, as defined in [24]. We believe the first published reference to an SDP in the context of packing was by Klein and Lu [17] in reference to the MAXCUT and coloring SDPs.

Our contributions in this paper are as follows.
(a) In section 2 we define the class of packing SDPs, and in section 2.1 we show that SDPs arising in many important optimization problems can be reformulated as packing SDPs. Using our algorithm we are able to solve all the packing SDPs in a unified manner.
(b) We propose a new technique for solving a packing SDP to an absolute error $\epsilon$.
Our solution approach relies on Lagrangian relaxation. We dualize the hard packing constraints to construct a relaxation where the primal feasible set is defined as $X = \{ X : X \succeq 0, \text{Tr}(X) \leq \omega_x \}$. In section 3, we show how to recover an $\epsilon$-optimal feasible solution from the optimal solution of the Lagrangian relaxation of the packing SDP. Unlike usual Lagrangian approaches which are only able to compute a bound for the optimal value, we produce a feasible solution. The results in this section apply to all packing SDPs.
In section 4 we consider the problem of computing an optimal solution of a Lagrangian relaxation for (1). We show that the resulting nonlinear Lagrangian objective function, which has form $\langle C, X \rangle - \sum_{i=1}^{m} v_i (g_i(X) - 1)$, can be linearized if we restrict the packing functions to the form
\begin{equation}
    g(X) = \max \left\{ \sum_{i=1}^{k} z_i (A_i, X) : Pz \leq d, z \geq 0 \right\},
\end{equation}
where the symmetric matrices $A_i \in \mathbb{R}^{n \times n}$, matrix $P \in \mathbb{R}^{\ell \times k}$, and vectors $d \in \mathbb{R}^{\ell}$ are such that $g(X) \geq 0$ for all $X \succeq 0$. The packing functions arising in the examples discussed in section 2.1 are all of this form. Note also that this set of functions is much larger than just functions of the form $g(X) = \max_{1 \leq i \leq m} (A_i, X)$. We show that Nesterov’s first-order procedure [22] can be used to efficiently compute a feasible, $\epsilon$-optimal solution for the Lagrangian relaxation of the packing SDP where all functions are of the form (2). Our algorithm is able to take advantage of any sparsity in the problem, i.e., sparsity in $C$ or sparsity in computing the packing functions $g_i(X)$. Since our method is based on the Nesterov procedure, the method computes an approximate solution even when the gradients are only approximately computed [8]. In addition, after reading in the problem data, the complexity of our method is logarithmic in the number of constraints.
(c) In section 5 we describe the complexity results for the specific instances discussed in section 2.1. We show that an $\epsilon$-optimal solution to the SDP relaxation to the MAXCUT problem can be computed in $O(nr^2 \log(n) \cdot \epsilon^{-1} \log^3(\epsilon^{-1}))$ time, where $r$ denotes the number of nonzero elements in the Laplacian matrix of the graph. The previous best-known result for a first-order technique is $O(nr \log^2(n) \cdot \epsilon^{-2})$ by Klein and Lu [17]. Recently, a result by Trevisan [29] has allowed a randomized algorithm of Arora and Kale [1] to be extended to general MAXCUT and runs in $O(r \log^2(n) \cdot \epsilon^{-6} \log^3(\epsilon^{-1}))$ time [15]. Thus, we have a trade-off—for moderate $\epsilon$ the Klein–Lu and Arora–Kale–Trevisan bounds are superior, but as $\epsilon$ decreases our approach is faster and is more suited for applications where one requires fairly accurate solutions of the MAXCUT relaxation.
We show that an \( \epsilon \)-optimal solution to the semidefinite relaxation for the graph coloring problem can be computed in \( \mathcal{O}(n^2 r \log(n) \cdot \epsilon^{-1} \log^3(\epsilon^{-1})) \) time. The Klein–Lu bound [17] for graph coloring is \( \mathcal{O}(nr \log^3(n) \cdot \epsilon^{-4}) \), which is significantly slower than their bound for Maxcut.

Our algorithm can compute \( \epsilon \)-approximations of the Lovász-\( \vartheta \) function [18] and Szegedy number [28] in \( \mathcal{O}(n^3 r \log(n) \cdot \epsilon^{-1} \log^3(\epsilon^{-1})) \) (i.e., the same as coloring) compared to the \( \mathcal{O}(n^3 (n^3 + r^3) \cdot \log(\epsilon^{-1})) \) runtime of the barrier method [21]. Thus, our tradeoff works in an opposite direction. For moderate \( \epsilon \) our bound is better for all graphs, and for dense graphs and moderate \( \epsilon \) our bound is much better. Chan, Chang, and Raman [5] extend the results of [1] to compute the Lovász-\( \vartheta \) function in \( \mathcal{O}(n^5 \cdot \epsilon^{-2}) \). Their method does not compute a feasible solution to the SDP for the Lovász-\( \vartheta \) function SDP, while our method does not.

We also show that our methods compute an \( \epsilon \)-optimal solution to the sparse principal component analysis (PCA) problem in \( \mathcal{O}(n^4 \sqrt{\log(n)} \cdot \epsilon^{-1}) \) which matches the best-known previous result for this problem [7]. Unlike the method in [7], our method always returns a feasible solution.

(d) In section 6.3, we show our solution algorithm actually runs \( \Omega(n) \) faster than the theoretical bounds predict on test cases from sparse PCA. We are able to solve SDPs with over \( 10^7 \) variables and constraints (i.e., problems where \( X \) is of dimension up to \( 6000 \times 6000 \)).

In [23] Nesterov describes how to extend the smoothing technique that he proposed in [22] to minimizing the maximal eigenvalue and the spectral radius of symmetric matrices. Nesterov establishes that one can efficiently compute an \( \epsilon \)-optimal solution to the nonsmooth semidefinite optimization problem by solving a sequence of penalized gradient descent problems where the step is penalized by an appropriately chosen smooth, strongly convex function. In the method proposed in [22, 23], the penalized gradient descent step has to be solved over the feasible set of the original nonsmooth problem. This restriction limits one to nonsmooth problems where the constraint set is “simple” [22, 23]. Note that computing a penalized gradient step over the feasible set of the packing SDP, as would be required by the method proposed in [23], is, in fact, as hard as solving the packing SDP. Thus, the method proposed in [22, 23] cannot be directly used to solve packing SDPs. A main contribution of our paper is that we show one can dualize the packing constraints and compute the smoothed gradient step for a large class of packing SDPs over the “simple” set \( \mathcal{X} = \{X : X \succeq 0, \text{Tr}(X) \leq \omega_X \} \) and still converge to an \( \epsilon \)-optimal feasible solution to the packing SDP in \( \mathcal{O}(\epsilon^{-1}) \) operations.

1.1. Notation and preliminaries. We denote vectors in lowercase bold (e.g., \( x \)), scalars in italics (e.g., \( x \) or \( X \)), matrices in uppercase bold (e.g., \( X \)), and sets in uppercase calligraphic font (e.g., \( \mathcal{X} \)). We use \( I_n \) and \( 0_n \) to denote \( n \) dimensional vectors of all ones and zeros, respectively, and we omit the subscript \( n \) when the dimension is clear. We follow the same convention with the identity matrix, \( I_n \), and the matrix of all ones, \( J_n \). When the dimension is clear, we define \( 0 \) as the matrix of all zeros and for all \( i \), we define \( e_i \) as the \( i \)th column of the identity matrix. We use \( S^n \) to denote the set of symmetric \( n \times n \) matrices and \( S^+_n \) to denote the cone of symmetric, positive semidefinite matrices, i.e., symmetric matrices with nonnegative eigenvalues. We denote the partial order on \( S^n \) induced by the cone \( S^+_n \) by \( \succeq \); i.e., \( A \succeq 0 \) indicates that the matrix \( A \) is symmetric and positive semidefinite, and \( A \succeq B \) indicates that \( A - B \succeq 0 \).
For a given vector \( \mathbf{v} \in \mathbb{R}^n \), we let \( \| \mathbf{v} \|_1 = \sum_{i=1}^{n} |v_i| \), \( \| \mathbf{v} \|_\infty = \max_{i=1,...,n} |v_i| \), and \( \| \mathbf{v} \|_2 = \sqrt{\sum_{i=1}^{n} v_i^2} \) denote the \( \ell_1 \), \( \ell_\infty \), and \( \ell_2 \) norms, respectively. We define the \( L_1 \), \( L_\infty \), and \( L_2 \) norms for a symmetric matrix \( \mathbf{A} \) as follows. Let

\[
\| \mathbf{A} \|_1 = \sum_{i=1}^{n} |\lambda_i(\mathbf{X})|, \quad \| \mathbf{A} \|_\infty = \max_{i=1,...,n} \{ |\lambda_i(\mathbf{A})| \}, \quad \| \mathbf{A} \|_2 = \left( \sum_{i=1}^{n} \lambda_i^2(\mathbf{A}) \right)^{\frac{1}{2}},
\]

where \( \{ \lambda_i(\mathbf{X}) : i = 1, \ldots, n \} \) denote the eigenvalues of \( \mathbf{A} \).

We call a differentiable, convex function \( f \) **strongly** convex with convexity parameter \( \sigma \) if

\[
f(y) \geq f(x) + \nabla f(x)^\top (y - x) + \frac{1}{2} \sigma \| y - x \|^2
\]
or equivalently if \( \nabla^2 f \) exists for all \( \mathbf{x} \) and \( \mathbf{z} \), \( \mathbf{z}^\top \nabla^2 f(\mathbf{x}) \mathbf{z} \geq \sigma \| \mathbf{z} \|^2 \). Note that the value of the convexity parameter \( \sigma \) depends on the particular norm \( \| \cdot \| \).

For \( \mathcal{Z} \subseteq \mathbb{R}^n \), we say that \( \mathbf{z}_a \in \mathcal{Z} \) is \( \epsilon \)-optimal in the **absolute** sense for the optimization problem \( \max_{\mathbf{z} \in \mathcal{Z}} \{ f(\mathbf{z}) \} \) if \( f(\mathbf{z}_a) \) is within an additive error \( \epsilon \) to the optimal value, i.e., if the inequality \( f(\mathbf{z}_a) \geq f^* - \epsilon \) is satisfied, where we define \( f^* = \max_{\mathbf{z} \in \mathcal{Z}} \{ f(\mathbf{z}) \} \). We say that \( \mathbf{z}_e \in \mathcal{Z} \) is \( \epsilon \)-optimal in the **relative** sense if \( f(\mathbf{z}_e) \geq (1 - \epsilon) f^* \), i.e., \( f(\mathbf{z}_e) \) is within a \( (1 - \epsilon) \) **multiplicative** factor of the optimal value. Note that the relative error measure has meaning only if \( f^* > 0 \). Suppose \( 0 < C \leq f^* \) and \( \mathbf{z}_a \) is \( \epsilon \)-optimal in the absolute sense. Then \( \mathbf{z}_e \) is \( \epsilon/C \) optimal in the relative sense since the definitions imply that \( f(\mathbf{z}_a) \geq f^* - \epsilon = f^* - C(\epsilon/C) \geq (1 - \epsilon/C) f^* \).

We use \( \mathcal{G} = (\mathcal{N}, \mathcal{E}) \) to denote an undirected graph with \( n = |\mathcal{N}| \) nodes and \( m = |\mathcal{E}| \) edges. We assume all graphs are connected which implies that \( m = \Omega(n) \).

2. **Packing SDP.** We begin by formally defining the packing SDP. Next, we show that many important optimization problems arising in combinatorial optimization, principal component analysis, and maximum variance unfolding can be reformulated as packing SDPs.

**Definition 1.** A function \( g : \mathcal{S}^n \to \mathbb{R} \) is called a packing function if

1. (convexity) \( g \) is convex.
2. (positive homogeneity on \( \mathcal{S}_+^n \) ) \( g(\beta \mathbf{X}) = \beta g(\mathbf{X}) \) for all \( \beta \geq 0 \), and \( \mathbf{X} \succeq 0 \).
3. (nonnegativity on \( \mathcal{S}_+^n \) ) \( g(\mathbf{X}) \geq 0 \) for all \( \mathbf{X} \succeq 0 \).

Packing functions are similar to gauge functions (see page 28 of [25] and [9])—note that unlike gauge functions we require only nonnegativity and positive homogeneity on \( \mathcal{S}_+^n \); e.g., \( g(\mathbf{X}) = \text{Tr}(\mathbf{X}) \) is a packing function but not a gauge function. Also, Minkowski functions of convex subsets of \( \mathcal{S}^n \) are packing functions but not necessarily gauge functions. Examples of packing functions include

\[
g(\mathbf{X}) = \langle \mathbf{A}, \mathbf{X} \rangle, \quad \mathbf{A} \succeq 0,
\]

\[
g(\mathbf{X}) = \sum_{i,j} |X_{ij}| = \max \left\{ \langle \mathbf{X}, \mathbf{Z} \rangle : |Z_{ij}| \leq 1 \ \forall i,j \right\},
\]

\[
g(\mathbf{X}) = \left\| \begin{pmatrix} \langle \mathbf{A}_1, \mathbf{X} \rangle \\ \vdots \\ \langle \mathbf{A}_k, \mathbf{X} \rangle \end{pmatrix} \right\|_\infty = \max \left\{ \sum_{i=1}^{k} z_i \langle \mathbf{A}_i, \mathbf{X} \rangle : \| \mathbf{z} \|_2 \leq 1 \right\}.
\]
The previous three packing functions are all special cases of the packing function

\[ g(X) = \max \left\{ \sum_{i=1}^{k} z_i \langle A_i, X \rangle : z \in P \subseteq \mathbb{R}^n_+ \right\}, \]

where the \( A_i \in \mathcal{S}^n \) for \( i = 1, \ldots, n \) and convex \( P \) are such that \( g(X) \geq 0 \) for all \( X \succeq 0 \).

4. \( g(X) = \|\lambda(X)\| \), where \( \lambda(X) \) denotes the vector of eigenvalues of \( X \) and \( \|\cdot\| \) is any vector norm.

The positive homogeneity condition (see list item 2 in Definition 1) is restrictive; it essentially restricts \( g \) to norm-like functions. For example, the function

\[ h(X) = \langle A, X \rangle + b \]

is not a packing function for any \( A \in \mathcal{S}^n \) and \( b \in \mathbb{R} - \{0\} \) since it violates positive homogeneity. General symmetric functions of eigenvalues are not packing functions; e.g., \( g(X) = \sum_i \lambda_i(X) \ln(\lambda_i(X)) \) is not a packing function \[23\].

**Definition 2.** A (packing SDP) is an optimization problem of the form

\[ \rho^* = \max \langle C, X \rangle \quad \text{s.t.} \quad g_i(X) \leq 1, \quad i = 1, \ldots, m, \]

\[ \text{Tr}(X) \leq \omega_x, \]

\[ X \succeq 0, \]

where \( C \succeq 0 \) and the functions \( g_i(X) \) are packing functions for all \( i = 1, \ldots, m \). We also allow the trace constraint \( \text{Tr}(X) \leq \omega_x \) to be an equality.

The trace constraint \( \text{Tr}(X) \leq \omega_x \) is equivalent to assuming the feasible region of the packing SDP (4) is compact. This is almost always true in problems of practical interest. The results in section 3 hold for all packing SDPs. In section 4 we restrict ourselves to packing functions of the form (2); i.e., we have

\[ g(X) = \max \left\{ \sum_{i=1}^{k} z_i \langle A_i, X \rangle : Pz \leq d, z \geq 0 \right\}, \]

where \( A_i \in \mathcal{S}^n, P \in \mathbb{R}^{\ell \times k}, \) and \( d \in \mathbb{R}^{\ell} \) are such that \( g(X) \geq 0 \) for all \( X \succeq 0 \). Note that \( g \) is a packing function in the form of (3) where the convex sets are polyhedral. All the packing constraints arising in the applications discussed in section 2.1 belong to this class of packing functions. The results in section 4 continue to hold for packing functions of the form

\[ g(X) = \max \left\{ \sum_{i=1}^{k} z_i \langle A_i, X \rangle : z \in \mathcal{Q} \right\}, \]

where \( \mathcal{Q} \) is compact and convex,

provided there exists a smooth, strongly convex function \( d(z) \) such that \( \min\{c^T z + d(z) : z \in \mathcal{Q}\} \) can be efficiently computed. We leave this extension to the reader.

2.1. **Instances of packing SDP.** Recall that \( \mathcal{G} = (\mathcal{N}, \mathcal{E}) \) denotes a graph with \( n = |\mathcal{N}| \) nodes and \( m = |\mathcal{E}| \) edges.
2.1.1. The MAXCUT SDP. The SDP relaxation to the MAXCUT problem introduced by Goemans and Williamson [11] is given by

\[
\begin{align*}
\text{max} & \quad \langle L, X \rangle \\
\text{subject to} & \quad \langle e_i e_i^\top, X \rangle = 1, \quad i = 1, \ldots, n, \\
& \quad X \succeq 0,
\end{align*}
\]

where \( L \) is the Laplacian of \( G \) and \( e_i \) is the \( i \)-th column of the identity matrix. The Laplacian of a weighted graph with nonnegative edge weights \( w_{ij}, (i,j) \in E \), is a symmetric matrix \( L = [L_{ij}] \), where

\[
L_{ij} = \begin{cases} 
-w_{ij}, & i \neq j, \\
\sum_{k=1}^n w_{ik}, & i = j.
\end{cases}
\]

We set \( w_{ij} = 0 \) when \((i,j) \notin E\) and \( i \neq j\). Then for any \( x \in \mathbb{R}^n \), (7) indicates that \( x^\top L x = 1/2 \sum_{i,j=1}^n w_{ij} (x_i - x_j)^2 \geq 0 \), i.e., \( L \succeq 0 \). Recall that we assume that \( G \) is connected, which implies that for all \( i = 1, \ldots, n \), there exists an index \( k \) such that \((i,k) \in E\) and \( w_{ik} > 0 \). Then (7) implies that \( L_{ii} = \sum_{k=1}^n w_{ij} > 0 \) for all \( i = 1, \ldots, n \).

Let \( D \) be a diagonal matrix with \( \text{diag}(L) \) as the main diagonal. Then the change of variables \( X = (\text{Tr}(D)) \cdot \frac{1}{\sqrt{\text{Tr}(D)}} Y D^{-\frac{1}{2}} \) implies that (6) is equivalent to

\[
\begin{align*}
\text{max} & \quad \langle L D, Y \rangle \\
\text{subject to} & \quad \frac{1}{\sqrt{\text{Tr}(D)}} \langle e_i e_i^\top, Y \rangle = \frac{D_{ii}}{\sqrt{\text{Tr}(D)}}, \quad i = 1, \ldots, n, \\
& \quad \text{Tr}(Y) \leq 1, \\
& \quad Y \succeq 0,
\end{align*}
\]

where \( L_D = D^{-1/2} LD^{-1/2} \) is the normalized Laplacian [26]. We claim that the packing SDP

\[
\begin{align*}
\text{max} & \quad \langle L_D, Y \rangle \\
\text{subject to} & \quad \frac{1}{\sqrt{\text{Tr}(D)}} \langle e_i e_i^\top, Y \rangle \leq 1, \quad i = 1, \ldots, n, \\
& \quad \text{Tr}(Y) \leq 1, \\
& \quad Y \succeq 0
\end{align*}
\]

is equivalent to (8). Since the constraints, \( Y_{ii} \leq \frac{D_{ii}}{\sqrt{\text{Tr}(D)}} \), for all \( i \), imply \( \text{Tr}(Y) \leq 1 \), the packing SDP (9) and the original SDP formulation (8) are equivalent unless there exists an optimal solution \( Y^* \) to (9) with an index \( i \) such that \( Y^*_{ii} < \frac{D_{ii}}{\sqrt{\text{Tr}(D)}} \). Suppose this is the case and define \( Y = Y^* + (\frac{D_{ii}}{\sqrt{\text{Tr}(D)}} - Y^*_{ii}) e_i e_i^\top \). By construction, \( Y \) is feasible for (8), and we have

\[
\langle L_D, Y \rangle = \langle L_D, Y^* \rangle + \left( \frac{D_{ii}}{\sqrt{\text{Tr}(D)}} - Y^*_{ii} \right) > \langle L_D, Y^* \rangle,
\]

a contradiction. Thus, it follows that the packing SDP (9) is equivalent to the MAXCUT SDP (8).

2.1.2. The Lovász-\( \vartheta \) function SDP. Lovász [18] defined the function \( \vartheta(G) \) as follows. Let

\[
\vartheta(G) = \max \langle J, X \rangle \\
\text{subject to} \quad x_{ij} = 0, \quad (i,j) \in E, \\
& \quad \text{Tr}(X) = 1, \\
& \quad X \succeq 0,
\]

where \( J \) is the incidence matrix of \( G \) and \( x_{ij} \) is the \( i,j \)-th entry of \( X \).
where $J \in \mathbb{R}^{n \times n}$ with all entries equal to 1. For each $(i, j) \in \mathcal{E}$, define $E^{(i,j)} = I + e_i e_j^\top + e_j e_i^\top$ and $F^{(i,j)} = I - (e_i e_j^\top + e_j e_i^\top)$. It is easy to show that $E^{(i,j)} \succeq 0$ and $F^{(i,j)} \succeq 0$ for all $(i,j) \in \mathcal{E}$. Using the fact that $\text{Tr}(X) = 1$, we can rewrite (10) as the packing SDP

$$
\vartheta(G) = \max \langle J, X \rangle \\
\text{s.t. } \langle E^{(i,j)}, X \rangle \leq 1, \quad (i,j) \in \mathcal{E}, \\
\langle F^{(i,j)}, X \rangle \leq 1, \quad (i,j) \in \mathcal{E}, \\
\text{Tr}(X) = 1, \\
X \succeq 0.
$$

Note that in reformulating (10) as the packing SDP (11) it was extremely important that we allow trace equality constraints in packing SDPs (see Definition 2).

A related quantity to $\vartheta(G)$ is Szegedy’s number $[28]$, defined as

$$
\vartheta^+(G) = \max \langle J, X \rangle \\
\text{s.t. } x_{ij} \leq 0, \quad (i,j) \in \mathcal{E}, \\
\text{Tr}(X) = 1, \\
X \succeq 0.
$$

Gvozdenović and Laurent [12] show that $\vartheta^+$ is a part of a family of graph parameters that approximate the clique and chromatic numbers. In particular, $\vartheta^+(G)$ is a better approximation to the clique number to $G$ than $\vartheta(G)$. We can reformulate (12) as the packing SDP

$$
\vartheta^+(G) = \max \langle J, X \rangle \\
\text{s.t. } \langle E^{(i,j)}, X \rangle \leq 1, \quad (i,j) \in \mathcal{E}, \\
\text{Tr}(X) = 1, \\
X \succeq 0.
$$

2.1.3. The coloring SDP. Karger, Motwani, and Sudan [16] describe the following SDP relaxation for the vertex graph coloring problem on $G$:

$$
\max \zeta \\
\text{s.t. } x_{ii} = 1, \quad i = 1, \ldots, n, \\
\zeta \leq -x_{ij}, \quad (i,j) \in \mathcal{E}, \\
X \succeq 0.
$$

For each $(i,j) \in \mathcal{E}$, define

$$
G^{(i,j)} = \frac{1}{2} \left( e_i e_i^\top + e_j e_j^\top - (e_i e_j^\top + e_j e_i^\top) \right) = \frac{1}{2} (e_i - e_j)(e_i - e_j)^\top \succeq 0.
$$

Then, for all $X$ feasible to (14), we have that $\langle G^{(i,j)}, X \rangle = 1 - x_{ij}$. Therefore, it follows that

$$
\zeta = \min_{(i,j) \in \mathcal{E}} -x_{ij} = \min_{(i,j) \in \mathcal{E}} \left\{ \langle G^{(i,j)}, X \rangle \right\} - 1 = \min \left\{ \sum_{(i,j) \in \mathcal{E}} w_{(i,j)} \langle G^{(i,j)}, X \rangle : \sum_{(i,j) \in \mathcal{E}} w_{(i,j)} = 1 \right\} - 1.
$$
From an argument similar to that used to show the equivalence of the Maxcut SDP to a packing SDP, it follows that (14) is equivalent to the max-min problem

$$\max \min \left\{ \sum_{(i,j) \in E} w_{ij} (G_{ij}, X) \right\}$$

s.t. \(x_{ii} \leq 1, \quad i = 1, \ldots, n,\)
\(X \succeq 0.\)

The optimization problem (15) is not a packing SDP. We compute an approximate solution to a packing SDP by using a Lagrangian relaxation, i.e., by converting the packing SDP into a max-min problem. In section 3, we describe this conversion and show that our solution algorithm can be easily adapted to solve a max-min problem of the form (15).

2.1.4. Single factor sparse PCA. PCA is a popular tool for data analysis and dimensionality reduction. It has applications throughout science and engineering. In essence, PCA finds linear combinations of the variables (the so-called principal components) that correspond to the directions of maximal variance in the data. Sparse PCA is concerned with computing principal components that are sparse, a highly desirable feature when working with high-dimensional data.

The single factor sparse PCA problem reduces to

$$\max x^\top C x$$

s.t. \(\|x\| = 1,\)
\(\text{Card}(x) \leq \kappa.\)

Here, \(C \in S^n_+\) is a given covariance matrix, \(\text{Card}(x)\) is a function that returns the number of nonzero components of \(x\), and \(1 < \kappa < n\) is a given parameter (\(\kappa = 1\) is the variable with maximum variance and \(\kappa = n\) is ordinary PCA, an eigenvalue problem). Further details about sparse PCA can be found in d’Aspremont et al. [7], who formulate the following SDP relaxation for the above nonconvex optimization problem:

$$\max \langle C, X \rangle$$

s.t. \(\frac{1}{\kappa} \sum_{ij} |X_{ij}| \leq 1,\)
\(\text{Tr}(X) = 1,\)
\(X \succeq 0.\)

The optimization problem (16) is a packing SDP. In [7] the authors approximately solve (16) by dualizing the cardinality constraint \(\sum_{ij} |X_{ij}| \leq \kappa:\) however, they do not guarantee that their solution is feasible. Our method computes feasible \(\epsilon\)-optimal solutions for the packing SDP (16).

2.1.5. Maximum variance unfolding. Maximum variance unfolding (MVU) (also called semidefinite embedding) is a technique introduced by Weinberger and Saul [32] for computing low-dimensional representations that preserve distances between “local” points while seeking to maximize the overall distance between all points.

Suppose we are given \(n\) data points \(D = \{y_i : i = 1, \ldots, n\} \subseteq \mathbb{R}^\ell\), where the dimension \(\ell \gg 1\). Let \(E \subset \{(i, j) : 1 \leq i < j \leq n\}\) denote a set of tuples. We call a pair \((i, j)\) “local” with respect to each other if and only if \((i, j) \in E\). The goal of the MVU
technique is to compute an $m$-dimensional representation of $D$ that preserves distances and minimizes the effective dimension of the resulting manifold, where $m \ll \ell$. To formulate as a mathematical program, denote the $m$-dimensional representation by $\{u_i : i = 1, \ldots, n\} \subset \mathbb{R}^m$. Weinberger and Saul [32] propose constructing such a manifold by solving the optimization problem

$$\max \sum_{i,j \in V} \|u_i - u_j\|^2 - \nu \sqrt{\sum_{(i,j) \in E} (\|u_i - u_j\|^2 - d_{ij})^2}$$

s.t. $\sum_{i=1}^n u_i = 0$, \hspace{1cm} (17)

where $\sum_{i=1}^n u_i = 0$ is a centering constraint. Since (17) is not a convex optimization problem, Weinberger and Saul [32] approximately solve (17) by constructing a semidefinite programming relaxation.

We present a slightly modified version of the relaxation developed in [32]. Let $U = [u_1, \ldots, u_{n-1}]$ and set $K = U^\top U$. For each $(i, j) \in E$, define $a_{i,j} \in \mathbb{R}^{n-1}$ as follows. Let

$$a_{i,j} = \begin{cases} e_i - e_j, & i, j \neq n, \\
-\frac{1}{n-1} \sum_{k=1}^{n-1} e_i, & j = n, \\
\frac{1}{n-1} \sum_{k=1}^{n-1} e_k - e_j, & i = n, \end{cases}$$

where $e_k$ denotes the $k$th column of $I_{n-1}$. Then, for each $i \neq j$, $u_i - u_j = U a_{i,j}$ and $\|u_i - u_j\|^2 = a_{i,j}^\top K a_{i,j} = \langle a_{i,j} a_{i,j}^\top, K \rangle$. In terms of the new variables, the optimization problem (17) is equivalent to

$$\max \min_{\|x\|_2 \leq 1} \left\{ \sum_{i,j \in V} a_{i,j} a_{i,j}^\top, K \right\} - \sum_{(i,j) \in E} z_{ij}(\langle a_{i,j} a_{i,j}^\top, K \rangle - d_{ij})$$

s.t. $\text{rank}(K) = m$, $\text{Tr}(K) \leq \tau$, $K \succeq 0$, \hspace{1cm} (18)

where $\tau = \sum_{i=1}^n \|y_i\|$. The semidefinite relaxation is obtained by relaxing the rank constraint on $K$ as in (16). The optimization problem (18) is a max-min problem which has the same structure as the Lagrangian relaxation we use in our solution algorithm for packing SDPs (see section 3).

2.1.6. Improving Laplacian eigenvalues and locally linear embedding using MVU. Laplacian eigenmaps, locally linear embedding, and isomaps are different techniques for computing low-dimensional representations for high-dimensional data that preserve proximity relations. Let

$$u_i = V y_i, \hspace{0.5cm} i = 1, \ldots, n,$$

where $V \in \mathbb{R}^{m \times \ell}$ denote the $m$-dimensional representation for the set of $\ell$-dimensional vectors $\{y_i : 1 \leq i \leq n\}$ computed by any data mining technique. Xiao, Sun, and Boyd [33] propose that this representation can be further refined via MVU postprocessing.
Recall that the MVU approach reduces to computing an appropriate Gram matrix for the data vectors. Given the representation matrix $V$, the data vectors are now $r$-dimensional vectors. In the Xiao, Sun, and Boyd [33] approach, the Gram matrix $K$ of the $n$ vectors is approximated by $K = V^T Q V$, where $Q \in \mathbb{R}^{r \times r}$ and $Q \succeq 0$. The MVU postprocessing step then reduces to the packing SDP

$$\begin{align*}
\text{max} & \quad \langle VV^T, Q \rangle \\
\text{s.t.} & \quad \langle V(e_i - e_j)(e_i - e_j)^T V^T, Q \rangle \leq d_{ij}, \quad (i, j) \in \mathcal{E}, \\
& \quad \text{Tr}(Q) \leq \tau, \\
& \quad Q \geq 0,
\end{align*}$$

where $\tau = \sum_{i=1}^n \|u_i\|$ and $d_{ij}, (i, j) \in \mathcal{E}$, denotes the bound on the distance between the “local” node pair $(i, j)$.

3. Lagrangian formulation and rounding. In this section, we show how to construct an $\epsilon$-approximate solution for the packing SDP (4) using Lagrangian penalization on the packing constraints. Penalizing the packing constraints converts the packing SDP into a primal-dual problem where both the primal and the dual feasible sets are “simple,” i.e., sets over which optimization is easy. Since the dual sets we use are bounded, the penalization results in a relaxation of the original packing SDP, and in this section we show how to convert approximate solutions to the relaxation into approximate solutions to the corresponding packing SDP. In section 4, we show that the Lagrangian relaxation can be efficiently solved for the class of packing functions defined in (2).

Define the Lagrangian function $\phi : \mathcal{S}^n \times \mathbb{R}^m \to \mathbb{R}$ of the packing SDP (4) as follows. For $(X, v) \in \mathcal{S}^n \times \mathbb{R}^m$, let

$$\phi(X, v) = \langle C, X \rangle - \sum_{i=0}^m v_i(g_i(X) - 1).$$

Consider computing a saddle-point (i.e., an exact solution) to the maximin problem

$$\max_{X \in \mathcal{X}} \min_{v \in \mathcal{V}} \phi(X, v),$$

where we need to specify the sets $\mathcal{X}$ and $\mathcal{V}$. Define

$$\mathcal{X} = \{X : X \succeq 0, \text{Tr}(X) \leq \omega_x\}.$$

Recall that we assume either the packing SDP (4) has the trace constraint $\text{Tr}(X) \leq \omega_x$ or such a bound is implied by the packing constraints. When the trace constraint in the packing SDP is an equality constraint, we set $\text{Tr}(X) = \omega_x$ in (21). If we let $\mathcal{V} = \mathbb{R}^m_+$, then (20) would be the Lagrangian dual for (4). However, we require a compact, i.e., bounded, set for $\mathcal{V}$. Thus, let

$$\mathcal{V} = \left\{v : v \succeq 0, \sum_{j=0}^m v_j \leq \omega_v\right\},$$

where

$$\omega_v = \max\{\langle C, X \rangle : X \in \mathcal{X}\} \leq \omega_x \lambda_{\max}(C) \leq \omega_x \text{Tr}(C).$$
We need the “diameter” $\omega_v$ of the dual set to be large enough to ensure that infeasible solutions to (4) are sufficiently penalized. The proof of Theorem 3 demonstrates that the bound $\omega_v$ in (23) is sufficiently large.

Let $\bar{v} \in \mathcal{V}$. Then for all $X$ feasible to the packing SDP (4), $\phi(X, \bar{v}) \geq \langle C, X \rangle$. Thus, we have

$$\max_{X \in \mathcal{X}} \phi(X, \bar{v}) \geq \max_{X \in \mathcal{X}} \langle C, X \rangle \geq \rho^*,$$

where the last inequality follows since the feasible region of the packing SDP (4), which is $\{X : g_i(X) \leq 1, i = 1, \ldots, m, \text{Tr}(X) \leq \omega_x, X \succeq 0\}$, is a subset of $\mathcal{X}$. Thus, it follows that

$$\max_{X \in \mathcal{X}} \min_{v \in \mathcal{V}} \phi(X, v) = \min_{v \in \mathcal{V}} \max_{X \in \mathcal{X}} \phi(X, v) \geq \rho^*,$$

where the equality follows from an appropriate saddle-point theorem applied to the function $\phi(X, v)$ and the inequality follows from (24). We refer to the max-min problem in (25) as the Lagrangian relaxation of the packing SDP, the maximization problem in $X$ as the primal problem, and the minimization problem in $v$ as the dual problem. We call a pair $(\bar{X}, \bar{v})$, $\bar{X} \in \mathcal{X}$, $\bar{v} \in \mathcal{V}$, an $\epsilon$-saddle-point for (20) if the pair satisfies

$$0 \leq \max_{X \in \mathcal{X}} \phi(X, \bar{v}) - \min_{v \in \mathcal{V}} \phi(\bar{X}, v) \leq \epsilon.$$

The main result in this section establishes that one can compute an $\epsilon$-optimal solution of the packing SDP (4) by appropriately scaling the $\epsilon$-saddle-point $\bar{X}$. We defer the problem of computing the $\epsilon$-saddle-point $(\bar{X}, \bar{v})$ to section 4.

**Theorem 3.** Fix $\epsilon > 0$. Let $(\bar{X}, \bar{v})$ denote any $\epsilon$-saddle-point to (20) with $\omega_v$ defined as in (23). Define $\bar{d} = \max_{i=1, \ldots, m} \{g_i(\bar{X})\}$ as the maximum value of the packing constraints. Then

$$\bar{X} = \begin{cases} (1/\bar{d})\bar{X}, & \bar{d} > 1, \\ \bar{X}, & \text{otherwise}, \end{cases}$$

is an $\epsilon$-optimal solution for the packing SDP (4).

**Proof.** When $\bar{d} < 1$, then $g_i(\bar{X}) \leq 1$ for all $i$; thus, $\bar{X} = \bar{X}$ is feasible. When $\bar{d} > 1$, the positive homogeneity property of the packing functions $g_i(\bar{X})$ implies that

$$1 \geq (\frac{1}{\bar{d}})g_i(\bar{X}) = g_i(\frac{1}{\bar{d}} \cdot \bar{X}) = g_i(\hat{X}).$$

Thus, $\hat{X}$ is always feasible to the packing SDP (4). Next, we show that $\hat{X}$ is $\epsilon$-optimal. Consider the following two cases:

(a) $\bar{d} \leq 1$. In this case,

$$\min_{v \in \mathcal{V}} \left\{ \sum_{i=0}^{m} v_i (1 - g_i(\bar{X})) \right\} = 0.$$

Thus,

$$\langle C, \hat{X} \rangle = \langle C, \bar{X} \rangle + \min_{v \in \mathcal{V}} \left\{ \sum_{i=0}^{m} v_i (1 - g_i(\bar{X})) \right\} = \min_{v \in \mathcal{V}} \phi(\bar{X}, v),$$

is an $\epsilon$-optimal solution for the packing SDP (4).
where the last equality follows from the definition of $\phi$. Since $(\mathbf{X}, \mathbf{v})$ is an $\epsilon$-saddle-point, it follows from (26) and (24) that

$$\min_{\mathbf{v} \in \mathcal{V}} \phi(\mathbf{X}, \mathbf{v}) \geq \max_{\mathbf{X} \in \mathcal{X}} \phi(\mathbf{X}, \mathbf{v}) - \epsilon \geq \rho^* - \epsilon.$$

(b) $d > 1$. Since $\mathbf{C} \succeq 0$, $\hat{\mathbf{X}} \succeq 0$, and $\frac{1}{d} \geq 1 - (d - 1)$ for all $d > 0$, we have that

$$\left\langle \mathbf{C}, \hat{\mathbf{X}} \right\rangle = \frac{1}{d} \left\langle \mathbf{C}, \mathbf{X} \right\rangle \geq \left\langle \mathbf{C}, \mathbf{X} \right\rangle - (d - 1) \left\langle \mathbf{C}, \hat{\mathbf{X}} \right\rangle \geq \left\langle \mathbf{C}, \mathbf{X} \right\rangle - (d - 1) \omega_v$$

(28)

(29)

$$= \left\langle \mathbf{C}, \mathbf{X} \right\rangle + \min_{\mathbf{v} \in \mathcal{V}} \left\{ \sum_{i=0}^{m} v_i (1 - g_i(\mathbf{X})) \right\}$$

$$= \min_{\mathbf{v} \in \mathcal{V}} \phi(\mathbf{X}, \mathbf{v}) \geq \rho^* - \epsilon,$$

where (28) follows from (23) since $\mathbf{X} \in \mathcal{X}$, (29) follows from the fact that $\omega_v(1 - d) = \min_{\mathbf{v} \in \mathcal{V}} \left\{ \sum_{i=0}^{m} v_i (1 - g_i(\mathbf{X})) \right\}$ whenever $d > 1$, and (30) follows from (26) and (24).

Thus, we have that $\mathbf{X}$ is a feasible, $\epsilon$-optimal solution to (4). \qed

Lagrangian relaxations typically yield good bounds but do not yield feasible solutions. Theorem 3 shows that by setting the “diameter” $\omega_v$ sufficiently large one can recover a feasible $\epsilon$-approximate solution for any packing SDP (4) from an $\epsilon$-saddle-point for (20). In the next section we show that for a restricted class of packing functions one can compute an $\epsilon$-saddle-point efficiently.

Theorem 3 can be used to convert $\epsilon$-saddle-points to $\epsilon$-approximate solutions for the packing SDPs for maximum variance unfolding and Laplacian eigenmaps (sections 2.1.5 and 2.1.6, respectively). However, Theorem 3 does not find feasible solutions for packing SDPs with a trace equality constraint. In the case of MAXCUT, relaxing the original trace equality constraint is equivalent to restricting the main diagonal to the ones vector. However, the objective function in this case is nondecreasing in the main diagonal, so a feasible, $\epsilon$-optimal solution can be calculated by just replacing the main diagonal with ones.

**Lemma 4.** Suppose $f : \mathcal{S}^n \to \mathbb{R}$ such that $f(\mathbf{Y} + \alpha \mathbf{e}_i \mathbf{e}_i^\top) \geq f(\mathbf{Y})$ for all $\mathbf{Y} \succeq 0$, $\alpha > 0$, and all canonical basis vectors $\mathbf{e}_i$, $i = 1, \ldots, n$. Let $\nu^* = \max\{ f(\mathbf{X}) : \text{diag}(\mathbf{X}) = 1, \mathbf{X} \succeq 0 \}$.

Suppose $\mathbf{X} \succeq 0$ such that $\text{diag}(\mathbf{X}) \leq 1$ and $f(\mathbf{X}) \geq \nu^* - \epsilon$ for $\epsilon > 0$; then $\mathbf{Y} = \mathbf{X} + \mathbf{I} - \mathbf{D}_\mathbf{X}$ is a feasible $\epsilon$-optimal solution (where $\mathbf{D}_\mathbf{X}$ is a diagonal matrix with $\text{diag}(\mathbf{X})$ along the main diagonal).

**Proof.** This follows directly from the fact that $\mathbf{I} - \mathbf{D}_\mathbf{X} \succeq 0$ and that $f(\mathbf{Y}) \geq f(\mathbf{X})$. \qed

Note that Lemma 4 can be used for both the MAXCUT packing SDP (in conjunction with Theorem 3) and the max-min optimization problem (15) for coloring.

Recall that the packing SDPs for the Lovász $\vartheta$-function, Szegedy’s number, and sparse PCA all have a trace equality constraint, so Theorem 3 does not apply. We therefore provide a more general “additive rounding” when the packing SDP with a trace equality constraint has a strictly feasible point.
Theorem 5. Suppose $Z$ is a strictly feasible solution to a packing SDP (4) with the trace equality constraint
\[ \text{Tr}(Z) = \omega_x, \quad g_i(Z) < 1 \quad \forall i = 1, \ldots, m. \]

Define the dual set parameter
\[ \omega_v = \frac{\rho_u - (C, Z)}{1 - g_{\max}(Z)}, \]
where for $X \in \mathcal{X}$, we set
\[ g_{\max}(X) \triangleq \max_{1 \leq i \leq m} \{ g_i(X) \} \]
and $\rho_u$ is any upper bound on $\rho^*$; in particular, we can set $\rho_u = (C, Z)$. Suppose that $(\bar{X}, \bar{v})$ is an $\epsilon$-optimal saddle-point and assume that $(C, Z) < (C, \bar{X})$ and $g_{\max}(\bar{X}) > 1$.\footnote{Otherwise, we just use $Z$ or $\bar{X}$ as our solution.}

Define
\[ \hat{X} = \frac{X + \beta(X)Z}{1 + \beta(X)}, \]
where for $X \in \mathcal{X}$ we set
\[ \beta(X) \triangleq \frac{g_{\max}(X) - 1}{1 - g_{\max}(Z)}. \]

Then $\hat{X}$ is a feasible $\epsilon$-optimal solution to (4) with $\text{Tr}(\hat{X}) = \omega_x$.

Proof. We first show that $\hat{X}$ is feasible. Since $Z$ is strictly feasible, we have $g_{\max}(Z) < 1$. By assumption, $g_{\max}(\bar{X}) > 1$ so $\beta(\bar{X}) > 0$. Thus, $\hat{X}$ is a convex combination of $\bar{X}$ and $Z$. Then $Z, \bar{X} \in \mathcal{X}$ and the convexity of $\mathcal{X}$ imply that $\hat{X} \in \mathcal{X}$, i.e., $\hat{X} \succeq 0$ and $\text{Tr}(\hat{X}) = \omega_x$. Since each of the packing functions $g_i(X)$ are convex, it follows that $g_{\max}(\hat{X})$ is also a convex function. Thus, we have
\[ g_{\max}(\hat{X}) \leq \frac{g_{\max}(\bar{X}) + \beta(\bar{X})g_{\max}(Z)}{1 + \beta(\bar{X})}. \]

Substituting for $\beta(\bar{X})$ we get
\[ g_{\max}(\hat{X}) \leq \frac{g_{\max}(\bar{X})(1 - g_{\max}(Z)) + g_{\max}(Z)(g_{\max}(\bar{X}) - 1)}{g_{\max}(\bar{X}) - g_{\max}(Z)} = 1. \]

Thus, $g_i(\hat{X}) \leq 1$ for all $i = 1, \ldots, m$.

We now show that $\hat{X}$ is $\epsilon$-optimal. Define
\[ \Psi(X) = \min_{v \in \mathcal{V}} \phi(X, v) = (C, X) - \omega_v \max\{0, g_{\max}(X) - 1\}, \]
where the last equality follows from the definition of the dual set $\mathcal{V}$. We first show that $\rho^* = \max_{X \in \mathcal{X}} \Psi(X)$. For a fixed $X \in \mathcal{X}$, define $\beta^+ = \max\{\beta(X), 0\}$ and
\[ \bar{Y} = \frac{X + \beta^+Z}{1 + \beta^+} \iff X + \beta^+Z = (1 + \beta^+)\bar{Y}. \]
Then $Y$ is feasible for (4). Also, by the definition of $\beta(X)$, it follows that

$$\Psi(X) - \rho^* = \langle C, X \rangle - \omega_v \max \{ 0, g_{\max}(X) - 1 \} - \rho^* = \langle C, X \rangle - \omega_v \max \{ \beta(X)(1 - g_{\max}(Z), 0) \} - \rho^*.$$

Since $g_{\max}(Z) < 1$, we can factor and then substitute $\rho_u - \langle C, Z \rangle$ for $\omega_v(1 - g_{\max}(Z))$ to obtain

$$\Psi(X) - \rho^* = \langle C, X + \beta^*Z \rangle - \beta^+ \rho_u - \rho^*.$$ 

Now we can use the definition of $Y$ to obtain

$$\Psi(X) - \rho^* = (1 + \beta^+) \langle C, Y \rangle - \beta^+ \rho_u - \rho^* = (1 + \beta^+) (\langle C, Y \rangle - \rho^*) - \beta^+ (\rho_u - \rho^*) \leq 0,$$

where the inequality follows since $Y$ is feasible for (4) and $\rho_u \geq \rho^*$. Then (25) implies that

$$\max_{X \in \mathcal{X}} \min_{v \in \mathcal{V}} \phi(X, v) = \rho^*.$$

Since $(\overline{X}, \overline{V})$ is an $\epsilon$-saddle-point,

$$\Psi(\overline{X}) = \min_{v \in \mathcal{V}} \phi(\overline{X}, v) \geq \max_{X \in \mathcal{X}} \phi(X, \overline{V}) - \epsilon \geq \rho^* - \epsilon.$$

Therefore, the definition of $\hat{X}$ implies that

$$\langle C, \hat{X} \rangle - \rho^* = (1 + \beta(\overline{X}))(\langle C, \overline{X} \rangle - \rho^*) + \beta(\overline{X})(\langle C, Z \rangle + \omega_v(1 - g_{\max}(Z))\rho^*) \geq - \epsilon + (\rho_u - \rho^*),$$

where (32) follows from the definition of $\beta(X)$ and (33) follows from the definition of $\omega_v$ in (31) and the fact that $\Psi(\overline{X}) = \langle C, \overline{X} \rangle - \omega_v(g_{\max}(\overline{X}) - 1) \geq \rho^* - \epsilon$. Thus, $\hat{X}$ is a feasible, $\epsilon$-optimal solution since we have

$$\langle C, \hat{X} \rangle \geq \rho^* - \frac{\epsilon}{1 + \beta(\overline{X})} \geq \rho^* - \epsilon. \quad \Box$$

Theorem 5 can be used to “round” $\epsilon$-saddle-points to both the sparse PCA and Szegedy’s number Lagrangian relaxations into feasible, $\epsilon$-optimal solutions to their respective packing SDPs. A version of Theorem 5 was also established by Z. Lu, Monteiro, and Yuan [19]. Note that the Lovász-$\theta$ function cannot be rounded with Theorem 5.

Recall that the semidefinite relaxation for graph coloring problem (15) and the semidefinite relaxation for the maximum variance unfolding problem (18) are not packing SDPs. However, the structure of the Lagrangian relaxation of these problems is identical to that of a packing SDP. For instance, the Lagrangian relaxation for the coloring problem

$$\max_{\{X \in \mathcal{S}^n : \text{Tr}(X) \leq n\}} \min \left\{ \begin{array}{l} \{w, z \geq 0 : \sum_{(i,j) \in \mathcal{E}} w_{ij} = 1, \sum_{i=1}^n z_i \leq \tau \} \\
\sum_{(i,j) \in \mathcal{E}} w_{ij} = 1, \sum_{i=1}^n z_i \leq \tau \end{array} \right\} \left\{ \sum_{(i,j) \in \mathcal{E}} w_{ij} \langle G_{ij}, X \rangle - \sum_{i=1}^n z_i (X_{ii} - 1) \right\},$$
where $\tau = \max \{ \min_{(i,j) \in E} \langle G_{i,j}, X \rangle : X \succeq 0, \text{Tr}(X) \leq n \} \leq 4$ has the same structure as the Lagrangian relaxation of the packing problem.

4. Solving the saddle-point problem. The saddle-point problem (20) is a game. An $\epsilon$-saddle-point for (20) is an $\epsilon$-equilibrium for this game. One could, in principle, use fictitious play [4] or similar methods to compute such an $\epsilon$-equilibrium. Since the general methods for computing $\epsilon$-equilibria in maximin games rely on subgradient descent and the primal-dual objective functions are nonsmooth, these general methods need $O(\frac{1}{\epsilon^2})$ iterations to converge [34].

4.1. Nesterov procedure for nonsmooth optimization. Nesterov proposed an iterative procedure for computing an $\epsilon$-saddle-point for the special case where each of the packing functions are linear (i.e., $g_i(X) = \langle A_i, X \rangle$ with $A_i \succeq 0$), i.e. saddle-point problems of the form

\[
\max_{X \in X} \min_{v \in V} \left\{ \langle C - \sum_{i=1}^m v_i A_i, X \rangle + \sum_{i=1}^m v_i \right\}.
\]

We note that Nesterov [23] has adapted his method from [22] to solve functions of form (34). We provide the relevant theorem from [22] for completeness.

**Theorem 6 (see [22]).** The Nesterov iterative procedure computes an $\epsilon$-saddle-point for (34) in $O(\epsilon^{-1} \cdot \sqrt{D_x D_v / \sigma_x \sigma_v})$ iterations where

(i) $\Omega^2 = \max \{ \|v\|_x \leq 1, \|X\|_x \leq 1 \} | \langle \sum_{i=1}^m v_i A_i, X \rangle |^2$ is the “size” of the constraint matrices and $\|\cdot\|_x$ and $\|\cdot\|_v$ are appropriate norms on the primal and dual spaces, respectively;

(ii) $D_x = \max_{X \in X} d_x(X)$ is the “diameter” of the set $X$ with respect to a strongly convex function $d_x$ that has a convexity parameter $\sigma_x$ and is nonnegative on the primal set $X$;

(iii) $D_v = \max_{v \in V} d_v(v)$ is the “diameter” of the set $V$ with respect to a strongly convex function $d_v$ that has a convexity parameter $\sigma_v$ and is nonnegative on the primal set $V$; and

(iv) in each iteration the procedure needs to compute an exact solution to problems of the form

\[
\max_{X \in X} \{ \langle \Gamma, X \rangle - \mu_x d_x(X) \}
\]

and

\[
\min_{v \in V} \left\{ \sum_{i=1}^m \gamma_i v_i + \mu_v d_v(v) \right\}
\]

for given $\Gamma \in \mathcal{S}^n$ and $\gamma \in \mathbb{R}^m$. The parameters $\mu_x$ and $\mu_v$ are functions of $\sigma_v, \sigma_x, \Omega, D_v$, and $\epsilon$ as described in Figure 1.

We call a strongly convex function that is nonnegative on a given convex set $S$ a prox-function for the set. Prox-functions ensure that both the primal and the dual optimization problems are smooth. In order for the Nesterov algorithm to be efficient, one should choose the prox-functions $d_x$ and $d_v$, so that the optimization problems (35) and (36) can both be solved in closed form. It is this requirement that restricts one to “simple” feasible sets $X$ and $V$. Another requirement on the prox-functions is that the associated “diameters” $D_x$ and $D_v$ are modest.
Nesterov Procedure

Set $N = \frac{O}{\beta D \delta \sigma v}$, $\mu_x = \frac{\epsilon}{\mu \sigma x}$, $\mu_v = \frac{O}{\mu v \sigma v} = \frac{OD}{\mu v \sigma v} \cdot \frac{1}{\epsilon}$.

Fix $(u^{(0)}, w^{(0)}) \in \mathcal{Y}$.

Set $X^{(0)} = \arg\max_{X \in \mathcal{X}} \left\{ \langle C, X \rangle - \sum_{i=1}^{m} \sum_{j=1}^{k_i} w_{ij}^{(0)} \langle A_{ij}, X \rangle - \mu_x d_x(X) \right\}$;

$\gamma_{ij}^{(0)} = \langle -A_{ij}, X^{(0)} \rangle$, $j = 1, \ldots, k_i$, $i = 1, \ldots, m$;

Set $(v_L^{(0)}, y_L^{(0)}) = \arg\min_{(v, y) \in \mathcal{Y}} \left\{ \frac{1}{2}(1, \gamma^{(0)})^\top (v, y) + \mu_v d_y(v, y) \right\}$;

for $t = 0$ to $N$

\begin{align*}
&\text{do} \\
&\quad \quad \text{Set } (u^{(t+1)}, w^{(t+1)}) = \left( \frac{2}{t+t+3} \right)(v_L^{(t)}, y_L^{(t)}) + \left( \frac{t+1}{t+t+3} \right)(v_L^{(t)}, y_L^{(t)}); \\
&\quad \quad X^{(t+1)} = \arg\max_{X \in \mathcal{X}} \left\{ \langle C, X \rangle - \sum_{i=1}^{m} w_{ij}^{(t+1)} \langle A_{ij}, X \rangle - \mu_x d_x(X) \right\}; \\
&\quad \quad \gamma_{ij}^{(t+1)} = \langle -A_{ij}, X^{(t+1)} \rangle, j = 1, \ldots, k_i, i = 1, \ldots, m; \\
&\quad \quad (\hat{u}^{(t+1)}, \hat{w}^{(t+1)}) \text{ is the minimum of} \\
&\quad \quad \left( \frac{2}{t+1} \right)(1, \gamma^{(t)}) - \nabla d_y((v_L^{(t)}, y_L^{(t)}))^\top (v, y) + d_y(v, y) \\
&\quad \quad \text{over } (v, y) \in \mathcal{Y}; \\
&\quad \quad (v_L^{(t+1)}, y_L^{(t+1)}) = \left( \frac{2}{t+3} \right)(\hat{u}^{(t+1)}, \hat{w}^{(t+1)}) + \left( \frac{t+1}{t+3} \right)(v_L^{(t)}, y_L^{(t)}); \\
&\quad \quad (v_G^{(t+1)}, y_G^{(t+1)}) \text{ is a solution to} \\
&\quad \quad \min_{(v, y) \in \mathcal{Y}} \left\{ \left( \sum_{i=0}^{t+1} \frac{1}{2} (1, \gamma^{(i)}) \right)^\top (v, y) + \mu_v d_y(v, y) \right\}; \\

&\text{return } \left( \Xi = \sum_{t=0}^{N} \frac{2(t+1)}{(N+1)(N+2)} X^{(t)}, (v_L^{(N)}, y_L^{(N)}) \right).
\end{align*}

Fig. 1. Nesterov procedure. Here, $(1, \gamma^{(i)})$ represents the gradient calculation, $(v_G^{(t)}, y_G^{(t)})$ and $(\hat{u}^{(t)}, \hat{w}^{(t)})$ are each calculated via (46), (47), and (48) for the prox-functions of the form described in (45).

As is typical in the Nesterov procedure, the numerical value of the constants $\mu_x = O(\epsilon)$ and $\mu_v = O\left( \frac{1}{\mu_x} \right) = O(\epsilon^{-1})$ are very different. The multiplier $\mu_x$ is the Lipschitz constant of a smoothed approximator of the saddle-point function, whereas $\mu_v$ is a penalty parameter on the change between dual iterates. In order to find an $\epsilon$-saddle-point, $\mu_x$ must be set to the order of $\epsilon$. This, in turn, requires the raising the smoothing constant $\mu_v$ to $O\left( \frac{1}{\mu_x} \right)$ (see [22] for further details). In practice, reducing $\mu_v$ can improve the runtimes of the algorithm (see also [30]).

4.2. Extension of Nesterov procedure to packing constraints. We extend Nesterov’s method to packing functions of the form described in (2). A large set of useful packing functions belong to this class—all the packing constraints that arise in the optimization problems described in section 2 are of this form. For this restricted class of packing functions, the Lagrangian function $\phi$ is given by

$$\phi(X, v, z_1, \ldots, z_m) = \langle C, X \rangle + \sum_{i=1}^{m} v_i \left( 1 - \sum_{j=1}^{k_i} z_{ij} \langle A_{ij}, X \rangle \right),$$

where for $i = 1, \ldots, m$, we denote $z_i \in \mathcal{P}_i = \{ z : A_i z \leq b_i \}$ as the variables associated with the $i$th packing function $g_i(X) = \max\{ \sum_{j=1}^{k_i} z_{ij} \langle A_{ij}, X \rangle : \mathcal{P}_i z_i \leq b_i \}$ and $v_i$ as the variables associated with the constraint $g_i(X) \leq 1$. Since $\phi$ is quadratic in $v$ and
where we are required to solve a smoothed version of the following problem:

\[
\max \phi(X, v, y_1, \ldots, y_m) = \langle C, X \rangle + \sum_{i=1}^{m} \left( v_i - \sum_{j=1}^{k_i} y_{ij} \langle A_{ij}, X \rangle \right).
\]

In terms of these new variables, the Lagrangian function is given by

\[
(38) \quad y_{ij} = v_i z_{ij}.
\]

Note that this linearization step works only because \( v \geq 0 \) and the saddle-point problem is minimizing over \( v \). Now we are in position to apply the Nesterov procedure to compute an \( \epsilon \)-saddle-point for the function \( \phi(X, v, y_1, \ldots, y_m) \) over the sets \( \mathcal{X} \times \mathcal{Y} \), where

\[
(40) \quad \mathcal{Y} = \left\{ (v, y_1, \ldots, y_m) : v \geq 0, \sum_{i=1}^{m} v_i \leq 1, P_i y_i \leq v_i b_i, i = 1, \ldots, m \right\}.
\]

In [22, 23] the primal feasible set is of the form \( \mathcal{X} = \{ X : X \succeq 0, \text{Tr}(X) \leq \omega_x \} \); however, the dual set is of the form \( \mathcal{Y} = \{ v : v \geq 0, \sum_{i=1}^{m} v_i \leq 1 \} \). We show that the Nesterov procedure can be extended to the larger set of dual spaces \( \mathcal{Y} \) in the form of (40). As we have indicated earlier, such a procedure is efficient only if one is able to construct prox-functions for the sets \( \mathcal{X} \) and \( \mathcal{Y} \). For the primal space, \( \mathcal{X} \), we have

\[
\max_{X \in \mathcal{X}} \phi(X, v, y_1, \ldots, y_m) = \omega_x \sum_{i=1}^{m} y_i + \omega_x \lambda_{\max} \left( C - \sum_{i=1}^{m} \sum_{j=1}^{k_i} y_{ij} A_{ij} \right),
\]

so the results of [23, section 4] can be used; i.e., we can use the spectral entropy function

\[
(41) \quad d_x(X) = \sum_{i=1}^{n} \lambda_i(X) \ln(\lambda_i(X)) + s_x \ln(s_x) - \omega_x \ln(\omega_x/(n + 1)).
\]

We note that the use of the spectral entropy function for smoothing is not new, e.g., see Ben-Tal and Nemirovski [3]. For completeness, we show in Appendix A, section A.2 that the “diameter” is \( D_x = \omega_x \ln(n + 1) \). What remains is to determine a prox-function for the dual set.

**4.2.1. Prox-function for the dual set \( \mathcal{Y} \).** In every step of the Nesterov procedure we are required to solve a smoothed version of the following problem:

\[
(42) \quad \min_{(v, y_1, \ldots, y_m) \in \mathcal{Y}} \left\{ \sum_{i=1}^{m} \left( v_i - \sum_{j=1}^{k_i} y_{ij} \gamma_{ij} \right) \right\},
\]

where \( \gamma_{ij}, i = 1, \ldots, m, j = 1, \ldots, k_i \), are parameters that change in each iteration. Here, we have \( y_{ij} = v_i z_{ij} \) as described in (38).

Recall that in this section we assume that for all \( i \), the packing function \( g_i(X) \) is of the form (2); i.e., for all \( j \), we are given matrices \( A_{ij} \) and \( P_i \) so that \( g_i(X) = \max \{ \sum_j z_j (A_{ij}, X) : P_i z \leq b_i \} \). Let \( d_i \) denote any prox-function such that the vector valued function

\[
(43) \quad f_i(\gamma) = \arg\min \left\{ \sum_{j=1}^{k} \gamma_j z_j + \mu_y d_i(z) : P_i z \leq b_i \right\}
\]
can be computed efficiently. Note that the optimization is over the \( z_i \) variables and not the \( y_i \) variables. Let \( d_v \) denote any prox-function that allows one to compute

\[
\text{(44)} \quad f_v(\gamma) = \arg\min \left\{ \sum_{j=1}^{k} \gamma_j v_i + \mu_y d_v(v) : v \in V \right\}
\]

in closed form. We smooth (42) using the prox-function

\[
\text{(45)} \quad d_y(v, y_1, \ldots, y_m) = \sum_{i=1}^{m} v_id_i(y_i/v_i) + d_v(v)
\]

to obtain the smooth optimization problem

\[
\text{(46)} \quad \min_{(v, y_1, \ldots, y_m) \in Y} \left\{ \sum_{i=1}^{m} (v_i - \sum_{j=1}^{k} y_{ij}\gamma_{ij}) \right\} + \mu_y d_y(v, y_1, \ldots, y_m) \}
\]

The optimization problem (46) can be decomposed into the form

\[
\text{(47)} \quad \min_{v \in Y} \left\{ \sum_{i=1}^{m} v_i \left( 1 - \max_{z_i \in P_i} \left\{ \sum_{j=1}^{k} y_{ij}\gamma_{ij} - \mu_y d_i(z_i) \right\} \right) + \mu_y d_v(v) \right\}
\]

Let \( \gamma_i = [\gamma_{i1}, \ldots, \gamma_{ik}]^T \), for \( i = 1, \ldots, m \), and \( \nu = [\nu_1, \ldots, \nu_m] \), where

\[
\nu_i = 1 - (\gamma_i^T f_i(\gamma_i) - \mu_y d_i(f_i(\gamma_i))), \quad i = 1, \ldots, m.
\]

Then the optimal solution to (46) is given by

\[
\text{(48)} \quad v^* = f_v(\nu), \quad y_i^* = v_i^* f_i(-\gamma_i), \quad i = 1, \ldots, m,
\]

where the functions \( f_i, i = 1, \ldots, m \), are defined in (43) and \( f_v \) is defined in (44).

All that remains to be shown is that the function \( d_y \) that satisfies (45) is, in fact, a prox-function for the dual set \( Y \). We can now use the following result of [14].

**Theorem 7** (see [14]). For all \( i = 1, \ldots, m \), suppose that \( d_i(z_i) \) is a prox-function for the set \( P_i = \{ z : P, z \leq b_i \} \), and \( d_v(v) \) is a prox-function for the set \( V \). Then the following statements are true.

(i) The function defined by \( d_y(v, y_1, \ldots, y_m) = \sum_{i=1}^{m} v_id_i(y_i/v_i) + d_v(v) \) is a prox-function of the set \( Y \). For all \( i = 1, \ldots, m \), let \( D_i \) be the “diameter” of the set \( P_i \) with respect to the prox-function \( d_i(z_i) \) and \( D_v \) be the “diameter” of the set \( V \) with respect to the prox-function \( d_v(v) \). Then the “diameter” of the set \( Y \) with respect to \( d_y \) is given by

\[
D_y = \max_{i=1, \ldots, m} \{ D_i \} + D_v.
\]

(ii) For \( i = 1, \ldots, m \), let \( \sigma_i \) be the convexity parameters of the prox-function \( d_i(z_i) \) with respect to the norm \( \| \cdot \| \), and define \( M_i = \max\{ \| z \| : z \in P_i \} \). Let \( \sigma_v \) be the convexity parameter of the prox-function \( d_v(v) \) with respect to the norm \( \| \cdot \|_v \). Then the convexity parameter of the prox-function \( d_y \) is

\[
\sigma_y = \frac{1}{\sum_{i=1}^{m} \frac{(1+M_i)}{\sigma_i} + \frac{1}{\sigma_v}}.
\]
We show in Appendix A, section A.1 that this prox-function has a convexity parameter (49). The natural prox-function for the set constructing prox-functions for each of the packing constraints and the set V. The results in the paper in a straightforward manner. Thus, our problem reduces to the dual solutions have form

\[\begin{aligned}
\gamma_i = \frac{1}{\omega_v} \\
\end{aligned}\]

The parameters are

\[\begin{aligned}
\gamma_v & = \frac{1}{\omega_v} & & \text{for } i = 1, \ldots, m.
\end{aligned}\]

The last result (iii) is not explicitly established in [14]; however, it follows from the results in the paper in a straightforward manner. Thus, our problem reduces to constructing prox-functions for each of the packing constraints and the set V. The natural prox-function for the set V is

\[\begin{aligned}
d_v(v) &= \sum_{i=1}^m v_i \ln(v_i) + s_v \ln(s_v) - \omega_v \ln(\omega_v/(m+1)).
\end{aligned}\]

We show in Appendix A, section A.1 that this prox-function has a convexity parameter \(\sigma_v = 1/\omega_v\) with respect to the \(\ell_1\)-norm and the “diameter” \(D_v = \omega_v \ln(m+1)\), and the dual solutions have form

\[\begin{aligned}
\gamma^* = \arg \min_v \{ \gamma^T v + \mu_d v \} \quad \Rightarrow \quad v_i^* = \frac{\omega_v e^{-\gamma_i/\mu_d}}{1 + \sum_{k=1}^m e^{-\gamma_k/\mu_d}}, \quad i = 1, \ldots, m.
\end{aligned}\]

Next we describe some prox-functions for the packing functions discussed in section 2.

1. \(g(X) = \langle A, X \rangle\) for \(A \succeq 0\). This function is smooth, and we do not need a prox-function.

2. \(g(X) = \sum_{i,j} |x_{ij}| = \max \{ \langle X, Z \rangle : |Z_{ij}| \leq 1 \forall i,j \}\). The simplest prox-function is \(d(Z) = \frac{1}{2} \sum_{i,j=1}^n |Z_{ij}|^2\). For this prox-function the parameters are

\[\begin{aligned}
D &= \frac{n^2}{2}, \quad \sigma = 1, \quad M = \max \{ \|Z\|_2 : Z \in P \} = n,
\end{aligned}\]

and the optimal solution, \(Z^* = \arg \max \{ \langle Z, X \rangle - \mu d(Z) : |Z_{ij}| \leq 1 \}\), is given by

\[\begin{aligned}
Z_{ij}^* = \text{sgn}(X_{ij}) \min \{ |X_{ij}|/\mu, 1 \}, \quad i, j = 1, \ldots, n.
\end{aligned}\]

3. Recall the infinity norm of a matrix-to-vector linear operator is a packing function defined as

\[\begin{aligned}
g(X) &= \left\| \begin{pmatrix} \langle A_1, X \rangle \\ \vdots \\ \langle A_k, X \rangle \end{pmatrix} \right\|_\infty = \max \left\{ \sum_{i=1}^k z_i \langle A_i, X \rangle : \|Z\|_2 \leq 1 \right\}.
\end{aligned}\]

The simplest prox-function is \(d(Z) = \frac{1}{2} \|Z\|_2^2\). For this prox-function the parameters are

\[\begin{aligned}
D &= \frac{1}{2}, \quad \sigma = 1, \quad M = 1,
\end{aligned}\]
and the optimal solution is
\[ z^* = \arg \max \left\{ \sum_{i=1}^{k} z_i \langle A_i, X_i \rangle - \mu d(z) : \|z\|_2 \leq 1 \right\} = \frac{1}{\mu + \beta} \left( \begin{array}{c} \langle A_1, X \rangle \\ \vdots \\ \langle A_k, X \rangle \end{array} \right), \]

where \( \beta = \max \{\|\langle A_1, X \rangle \ldots \langle A_k, X \rangle\|_2 - \mu, 0\} \).

Theorem 7 allows one the flexibility of independently choosing approximate prox-functions for each of the packing functions and the set \( V \). However, this flexibility has the tradeoff that the convexity parameter \( \sigma_y \) is typically very small. Consequently, the number of iterations required to converge to an \( \epsilon \)-optimal solution increases, and the numerical stability of the algorithm can be adversely affected. Therefore, for certain applications it might be more efficient and numerically stable to directly define a prox-function on the \( Y \) space.

4.3. Solution algorithm for packing SDPs. The algorithm for solving our saddle-point problems (37) is described in Figure 1. After executing the Nesterov procedure, we then apply Theorem 3, Lemma 4, and/or Theorem 5 as appropriate. We have made a few modifications to the standard version of the Nesterov procedure. We iterate in the dual space, i.e., in \( Y \), and then compute the approximate primal solution \( X \) by aggregating over all gradients. We compute the iterate \( y^{(k)} \) using the Bregman distance associated with the prox-function \( d_y \). For prox-functions of the form (45), the dual update decomposes into separate updates of the \( v \) and \( z \) variables (see (47) and (48) for details).

5. Complexity results for specific packing SDPs.

5.1. MAXCUT, graph coloring, and Lovász-\( \theta \) function. Recall that the packing SDP formulation of the MAXCUT problem is given by
\[ \rho^* = \max \langle L_D, X \rangle \]
\[ \text{s.t. } \frac{\text{Tr}(D)}{d_i} \langle e_i e_i^\top, X \rangle \leq 1, \quad i = 1, \ldots, n, \]
\[ \text{Tr}(X) \leq 1, \]
\[ X \succeq 0, \]
where \( L_D = D^{-\frac{1}{2}} D^2 D^{-\frac{1}{2}} \) denotes the normalized Laplacian. Note that \( \text{diag}(L_D) = I \) holds. Then since \( D / \text{Tr}(D) \) is feasible to the MAXCUT problem, it follows that \( \rho^* \geq 1 \). The trace constraint and Lemma 1.7 of [6] imply \( \omega_x = 1 \) and \( \omega_v = 2 \), respectively. Letting \( C = D^{-1/2} L D^{-1/2} \), the Lagrangian relaxation of this packing SDP is
\[ \max_{X \in X} \min_{v \in V} \left\{ 1^\top v + (C - A(v), X) \right\}, \]
where \( A(v) \) denotes a diagonal matrix with \( \frac{\text{Tr}(D)}{d_i} v_i \) along the main diagonal. We use the prox-function \( d_x(X) = \sum_{i=1}^{n} \lambda_i(X) \log(\lambda_i(X)) \) and the norm
\[ \|X\|_x = \sum_{i=1}^{n} |\lambda_i(X)| \]
for the \( X \)-space and the prox-function \( d_v(v) = \sum_{i=1}^{n} v_i \log(v_i) \) and the norm \( \|v\|_v = \sum_{i=1}^{n} |v_i| \) for the \( V \)-space. For these prox-functions, we have
\[ D_x = \log(n + 1), \quad D_v = 2 \log(n + 1), \]
and for these norms, we have

\[ \Omega^2 = \max_{\|X\|_x \leq 1} \max_{\|v\|_v \leq 1} \left( \sum_{i=1}^{n} \frac{\text{Tr}(D)}{d_i} (v_i X_{ii}) \right)^2 \leq (\text{Tr}(D))^2 \leq (2r)^2, \quad \sigma_x = 1, \quad \sigma_v = 1/2. \]

The Nesterov procedure and rounding via Theorem 3 and Lemma 4 require \( \mathcal{O}(r \log(n) \cdot \epsilon^{-1}) \) iterations to compute an \( \epsilon \)-approximate solution in the absolute sense. Since \( \rho^* \geq 1 \), it follows that such a solution is also \( \epsilon \)-approximate in the relative sense. Each iteration of the Nesterov procedure requires us to solve one problem of the form (36) and two optimization problems of the form (35). Thus, we have the following result.

**Corollary 8.** The complexity of computing an \( \epsilon \)-optimal solution in the relative sense for the MAXCUT problem using the Nesterov procedure and rounding is \( \mathcal{O}(nr^2 \log(n) \cdot \epsilon^{-1} \log^3(\epsilon^{-1})) \), where \( r \) denotes the total number of nonzero elements in the Laplacian matrix \( L \).

Recall that the Lagrangian relaxation of the packing SDP formulation for the graph coloring problem is given by

\[
\begin{align*}
\max_{\{X \geq 0 : \text{Tr}(X) \leq n\}} \min_{(w,z) \in \mathcal{W}} \left\{ \sum_{(i,j) \in E} w_{ij} \langle G_{ij}, X \rangle - \sum_{i=1}^{n} z_i (X_{ii} - 1) \right\},
\end{align*}
\]

where \( \tau = \max\{ \min_{(i,j) \in E} \langle G_{ij}, X \rangle : X \geq 0 \text{Tr}(X) \leq n \} \leq 4 \) and \( \mathcal{W} = \{(w,z) \geq 0 : \sum_{(i,j) \in E} w_{ij} = 1, \sum_{i=1}^{n} z_i \leq \tau \} \). We use the prox-function

\[ d_x(X) = \sum_{i=1}^{n} \lambda_i(X) \log(\lambda_i(X)) \]

and the norm \( \|X\|_x = \sum_{i=1}^{n} \lambda_i(X) \| \) for the primal space and the prox-function

\[ d_y(w,v) = \sum_{(i,j) \in E} w_{ij} \log(w_{ij}) + \sum_{i=1}^{n} v_i \log(v_i) \]

and the norm \( \|(w,v)\|_v = \sum_{(i,j) \in E} |w_{ij}| + \sum_{i=1}^{n} |v_i| \) for the dual space. For these prox-functions, the “diameters” are

\[ D_x = n \log(n+1), \quad D_v = \log(r) + \log(n+1) \leq 2 \log(n+1), \]

where in this case the sparsity equals the number of edges, i.e., \( r = m \). For these norms, the convexity parameters are given by \( \sigma_x = 1/n, \sigma_v = 1, \) and

\[ \Omega^2 = \max_{\|X\|_x \leq 1} \max_{\|(w,v)\|_v \leq 1} \left( \sum_{(i,j) \in E} w_{ij} \langle G_{ij}, X \rangle - \sum_{i=1}^{n} z_i (X_{ii}) \right)^2 \leq 4. \]

The Nesterov procedure and rounding via Theorem 3 and Lemma 4 require \( \mathcal{O}(n \log(n) \cdot \epsilon^{-1}) \) iterations to compute an \( \epsilon \)-approximate solution in the absolute sense. Karger, Motwani, and Sudan [16] establish that \( \rho^* \geq 1/c^* \), where \( c^* \) denotes the optimal number of colors required to color the graph. Thus, an \( \epsilon \)-approximate solution in the absolute sense is \((c^* \epsilon)\)-approximate in the relative sense. Each iteration of the Nesterov
procedure requires us to solve one problem of the form (36) and two optimization problems of the form (35). By Corollary 14 we have the following result.

**Corollary 9.** The complexity of computing an ε-optimal solution for the graph coloring SDP using the Nesterov procedure is \( \mathcal{O}(n^2r \log(n) \cdot \epsilon^{-1} \log^3(\epsilon^{-1})) \), where \( r \) denotes the total number of edges in the graph.

Recall that the packing SDP formulation for the Lovász-θ function is given by

\[
\vartheta(G) = \max \ \langle J, X \rangle \\
\text{s.t.} \quad \langle E^{(i,j)}, X \rangle \leq 1, \quad (i, j) \in E, \\
\langle F^{(i,j)}, X \rangle \leq 1, \quad (i, j) \in E, \\
\text{Tr}(X) = 1, \\
X \succeq 0.
\]

We use the prox-function \( d_x(X) = \sum_{i=1}^{n} \lambda_i(X) \log(\lambda_i(X)) \) and the norm \( \|X\|_x = \sum_{i=1}^{n} |\lambda_i(X)| \) for the primal space. For the dual space we use the prox-function \( d_y(v, w) = \sum_{(i,j) \in E} w_{ij} \log(w_{ij}) + \sum_{(i,j) \in E} v_{ij} \log(v_{ij}) \), where \( w \) are the dual multipliers for the \( \langle E^{(i,j)}, X \rangle \leq 1 \) constraints and \( v \) are the dual multipliers for the \( \langle F^{(i,j)}, X \rangle \leq 1 \) constraints. We use the norm \( \|(w, v)\|_v = \sum_{(i,j) \in E} |w_{ij}| + \sum_{i=1}^{n} |v_i| \) for the dual space. For these prox-functions, the “diameters” are given by

\[
D_x = \log(n+1), \quad D_v = n \log(2n+1)
\]

where, as before, \( r = m \). For these norms, the convexity parameters are given by

\[
\Omega^2 = 1, \quad \sigma_x = 1, \quad \sigma_v = 1/n.
\]

The Nesterov procedure requires \( \mathcal{O}(n \log(n) \cdot \epsilon^{-1}) \) iterations to approximate \( \vartheta(G) \) to within \( \epsilon \) in the absolute sense. Since \( \frac{1}{n}I \) is feasible to (10), it follows that \( \vartheta(G) \geq 1 \), so an absolute \( \epsilon \)-approximation is also \( \epsilon \)-approximate in the relative sense. Each iteration of the Nesterov procedure requires us to solve one problem of the form (36) and two optimization problems of the form (35). An analogous argument also works for Szegedy’s number, \( \vartheta^+ \). Moreover, Theorem 5 can be used to round the SDP solution to feasibility, as \( \frac{1}{n}(I - \frac{1}{n}J) \) is a strict feasible solution to (13). Thus, we have the following result.

**Corollary 10.** The complexity of approximating the Lovász-θ function and Szegedy’s number of a graph to within \( \epsilon \) (absolutely or relatively) using the Nesterov procedure is \( \mathcal{O}(n^2r \log(n) \cdot \epsilon^{-1} \log^3(\epsilon^{-1})) \), where \( r \) denotes the total number of edges in the graph.

We compare the best known algorithms for coloring, MAXCUT, the Lovasz-θ function and Szegedy’s number in Table 1. For moderate \( \epsilon \approx 10^{-3} \) and dense graphs \( r = \Omega(n^{1+\epsilon}) \), the packing SDP-based methods are superior to other methods available in the literature. Another significant feature of our method is that we treat a large class of SDPs in a unified manner.

**5.2. Sparse PCA.** In this application the packing function is given by

\[
g(X) = \frac{1}{\kappa} \sum_{i,j} |X_{ij}| = \max_{\{Y : \|Y\|_2 \leq 1\}} \left\{ \frac{1}{\kappa} \langle Y, X \rangle \right\}.
\]
Therefore, (39), (40), and (47) imply that the Lagrangian relaxation of the sparse PCA packing SDP (16) is given by

\[
\max_{X} \min_{(v, Y) \in \mathcal{Y}} \left\{ \left\langle C - \frac{1}{\kappa} Y, X \right\rangle + v \right\},
\]

where the dual set is of the form \( \mathcal{Y} = \{(v, Y) : 0 \leq v \leq 1, |Y_{ij}| \leq v\} \) and the primal set is of the form \( \mathcal{X} = \{X : X \succeq 0, \text{Tr}(X) = 1\} \). In the sparse PCA formulation one typically assumes that \( C \) has been scaled to ensure that \( \text{Tr}(C) = 1 \); therefore, we have that \( \omega_x = \max\{(C, X) : X \succeq 0, \text{Tr}(X) = 1\} = 1 \). For the primal set \( \mathcal{X} \), we use the entropy prox-function

\[
d_x(X) = \sum_{i=1}^{n} \lambda_i(X) \log(\lambda_i(X)), \quad \|X\|_x = \sum_{i=1}^{n} |\lambda_i(X)|,
\]

which has a “diameter” \( D_x = \log(n+1) \) and convexity parameter \( \sigma_x = 1 \). For the set \( \mathcal{Y} \), we use the quadratic prox-function

\[
d_y(v, Y) = \frac{1}{2} v^2 + \frac{1}{2} \sum_{ij} |Y_{ij}|^2, \quad \|(v, Y)\|_y = \left( |v|^2 + \sum_{ij} |Y_{ij}|^2 \right)^{\frac{1}{2}}.
\]

Since the prox-function \( d_y(v, Y) \) is not of the form \( v d_x(Y/v) + d_x(v) \), we cannot use Theorem 7 to compute the “diameter” \( D_y \), the convexity parameter \( \sigma \), and the parameter \( \Omega \). In Lemma 15 in Appendix C, section C.1 we directly compute that these parameters are \( D_y = n^2, \sigma_y = 1 \), and \( \Omega = 1 \).

We show in Appendix C, section C.1 that the optimization problem

\[
\min_{(v, Y) \in \mathcal{Y}} \left\{ \langle X, Y \rangle + \ell v + \mu_y d_y(v, Y) \right\}
\]

can be solved with an active set method in \( O(n^2 \log(n)) \) time. Therefore, the complexity per iteration is dominated by the cost of computing the exponential of a matrix that is generally dense, so the full eigenvalue-eigenvector decomposition is, theoretically, best. Since \( I \) is a strictly feasible solution, we can use Theorem 5 to round.

**Corollary 11.** The complexity of computing an \( \epsilon \)-optimal solution for the sparse PCA problem using the Nesterov procedure with rounding is \( O(n^4, \sqrt{\log(n)} \cdot \epsilon^{-1}) \).

Our runtime matches the best known previous result of [7]. However, the procedure in [7] does not yield a feasible solution for the relaxation — one needs to conduct a one-dimensional search over \( v \) to obtain a feasible solution.

6. Numerical experiments. We tested our general algorithm for solving packing SDPs on the sparse PCA problem (16). We describe our implementation in detail in section 6.1. We tested the runtime performance of our implementation on random instances generated in a manner similar to that described in [35] (see also [7]). We describe data generation in section 6.2 and report the results of our numerical experiments in section 6.3. The code for both the solution algorithm and data generation was written completely in MATLAB [20]. Each experiment was run in MATLAB release R2009a on an Opteron 2.6 GHz dual-core two processor machine with 20 GB of RAM and the default multithreading capabilities of MATLAB enabled. Since we use the multithreading capability of MATLAB, we report the actual time (using MATLAB functions tic and toc). For the per iteration cost, we report the more conservative CPU time, which includes the overhead incurred by the multithreading.

6.1. Implementation details.

Initial dual iterate. Our solution algorithm for packing SDP needs an initial feasible dual solution. In our numerical experiments, we used the initial solution \( v = 0.8 \) and \( Y = 0.2 \text{sgn}(C) \), where \( \text{sgn}(C) \) is a matrix with \( \text{sgn}(C_{ij}) \) as the \((i,j)\)th entry.

Primal iterate, dual gradients, and the matrix exponential. The dual gradient is given by the optimal solution of the smoothed primal optimization problem

\[
\max_{X \in \mathcal{X}} \left\{ \left\langle C - \frac{1}{\kappa} Y^{(k)}, X \right\rangle + \mu_x d_x(X) \right\},
\]

where the prox-function \( d_x(X) = \sum_{i=1}^n \lambda_i(X) \log(\lambda_i(X)) \) and \( \{\lambda_i\} \) denotes the set of eigenvalues of \( X \). The optimal solution is

\[
X^* = \frac{\mu^{-1}_x (C - \frac{1}{\kappa} Y^{(k)})}{\text{Tr} \left( \frac{1}{e^{x\kappa}} (C - \frac{1}{\kappa} Y^{(k)}) \right)} = \frac{V e^{\kappa Y} V^T}{\sum_i e^{\omega_i}} = \frac{V e^{\kappa Y} V^T}{\sum_i e^{(\omega_i - \nu)}},
\]

where \( \Omega = \text{diag}(\omega) \) and \( \omega_i \) is the \(i\)th eigenvalue of the matrix \( \mu_x^{-1}(C - \frac{1}{\kappa} Y^{(k)}) \) and \( \nu \) is an arbitrary user-defined parameter. Shifting eigenvalues by \( \nu \) was suggested in section 5.2 in [22].

We computed \( X^* \) using three different methods: the standard matrix exponential calculator \texttt{expm} in MATLAB, a full eigenvalue-vector decomposition, and a partial eigenvalue-vector decomposition (using Lanczos iterations). The latter two methods allow for a finer control over the precision of the exponential computation. We found that the full eigenvalue-vector decomposition performed best with \( \nu = \max_i \omega_i \). We also found that \( \mu_x < 0.02 \) exceeded the precision capabilities of all methods; therefore, we use \( \mu_x \in \{0.03, 0.04\} \) depending on the problem class. The quadratic prox-function used in the dual space was stable with respect to the \( \mu_y \) parameter. An interesting open direction would be to use a quadratic prox-function for the primal optimization step.

Scaling covariance matrix \( C \). Typically in sparse PCA applications one assumes that the matrix \( C \) is scaled so that \( \text{Tr}(C) = 1 \). We found that this scaling did not perform well in our numerical experiments. The main reason was the numerical difficulties in computing the exponential of a dense matrix. Since the primal parameter was set so that \( \mu_x \geq 0.03 \), the primal iterate \( X^{(k)} \), i.e., the smoothed optimal solution, is not very close to the true (nonsmooth) optimal solution. We found that this inaccuracy did not hamper the progress of the algorithm when the dual iterate was set so that \( (\nu^{(k)}, Y^{(k)}) \neq (0, 0) \). However, when the dual iterates were small, i.e.,
\((\nu(k), \mathbf{Y}(k)) \approx (0, 0)\), we need to ensure that the primal iterate

\[
\mathbf{X}_C = \arg \max_{\mathbf{X} \in \mathcal{X}} \left\{ \langle \mathbf{C}, \mathbf{X} \rangle - \mu_x d_x(\mathbf{X}) \right\}
\]

is close to the true (nonsmooth) optimal solution in order to correctly compute the dual iterates. If not, it is possible that the smoothed solution is primal feasible whereas the true solution is, in fact, infeasible. In such a case, the successive dual iterates remain close to zero, and the algorithm progresses slowly. We can avoid this problem by either decreasing \(\mu_x\) or scaling up the matrix \(\mathbf{C}\). In either case, we increase the computational cost since the effective Lipschitz constant increases. We chose to scale up \(\mathbf{C}\) because such a scaling significantly affects only the computational cost iterate when \((\nu(k), \mathbf{Y}(k)) \approx (0, 0)\). We scale \(\mathbf{C}\) by \(\nu/\text{Tr}(\mathbf{C})\), where \(\nu\) is chosen so that \(g(\mathbf{X}_C) \in [1 + \delta, 1 + \gamma]\) for some positive \(\delta < \gamma\). In our numerical experiments we set \(\delta = .3\) and \(\gamma = 4\). Since each iteration of the search for the correct scaling is equivalent (modulo a constant) to one step of the algorithm, we include these search iterations in our runtimes and iteration counts (which added 4–9 iterations to our iteration counts).

**Termination conditions.** We used several termination conditions concurrently.

(a) At any iteration the duality gap is

\[
\eta(t) = \min_{(\nu, \mathbf{X}) \in \mathcal{Y}} \left\{ \langle \mathbf{C}, \mathbf{X}(t) \rangle - \sum_{ij} \langle y_{ij} \mathbf{A}_{ij}, \mathbf{X}(t) \rangle + \sum_i v_i \right\} - \max_{\mathbf{X} \in \mathcal{X}} \left\{ \langle \mathbf{C} - \sum_{ij} y(t)_{ij}, \mathbf{X} \rangle + v(t) \right\} = \left( \langle \mathbf{C}, \mathbf{X}(t) \rangle - \max \left\{ 0, 1 - \sum_{ij} |X_{ij}(t)| \right\} \right) - \left( v(t) \max \{0, \lambda_{\max}(\mathbf{C} - (1/k)\mathbf{Y}(t)) \} \right).
\]

We terminate whenever the duality gap satisfies \(\eta(t) \leq \epsilon\). We “round” the output \(\mathbf{X}\) from the Nesterov procedure into a feasible solution \(\hat{\mathbf{X}}\) using Lemma 16 in Appendix C, section C.2.

(b) Let \(\mathbf{X}^{(k)}\) denote the primal iterate computed in iteration \(k\). Let

\[
\mathbf{X}^{(t)} = \sum_{k=0}^{t} \frac{2(k+1)}{(t+1)(t+2)} \mathbf{X}^{(k)}
\]

denote the primal saddle-point solution returned by the Nesterov procedure if it were to be terminated at iteration \(t\). Suppose \(\mathbf{X}^{(t)}\) is \(\delta\)-feasible, i.e., \(g(\mathbf{X}^{(t)}) \leq 1 + \delta\), and the cumulative infeasibility satisfied \(\sigma(t) = \sum_{k=0}^{t} \frac{2(k+1)}{(t+1)(t+2)} (\nu(k) - \frac{2}{\kappa} \langle \mathbf{Y}(k), \mathbf{X}^{(k)} \rangle) \leq \delta\). Then Lemma 17 in Appendix C, section C.2 shows how to construct a feasible solution \(\hat{\mathbf{X}}\) such that \(\langle \mathbf{C}, \hat{\mathbf{X}} \rangle \geq (1 - \frac{\epsilon \delta}{\kappa})(\langle \mathbf{C}, \mathbf{X}^{*} \rangle - \frac{\kappa}{2} - \delta)\). Thus, we are guaranteed that \(\hat{\mathbf{X}}\) is \(\epsilon\)-optimal if we set \(\delta = \epsilon(\kappa - 1)/2((\nu + 1)\kappa - 1)\), where \(\nu\) denotes the factor by which we scale \(\mathbf{C}\).

**6.2. Problem data.** We focused our experiments on random SDP instances where the number of components and their sparsity were known. The following instance generator was introduced in [35] (see also [7]).
(i) **Descriptive variables.** The family is generated from the random variables

\[ Y_1 \sim N(0, \sigma_1^2), \quad Y_2 \sim N(0, \sigma_2^2), \quad D = w_1 Y_1 + w_2 Y_2 + \delta, \quad \delta \sim N(0, \sigma_3^2) \]

where \( Y_1, Y_2 \) and \( \delta \) are independent random variables and \( N(\mu, \sigma^2) \) denotes a normal distribution with mean \( \mu \) and variance \( \sigma^2 \); and

(ii) **Observations.** The family has the following “observed variables”:

\[ X_i = \begin{cases} 
Y_1 + \eta_i, & i = 1, 2, 3, 4, \\
Y_2 + \eta_i, & i = 5, 6, 7, 8, \\
D + \eta_i, & i = 9, 10,
\end{cases} \]

where each \( \eta_i \sim N(0, 1) \). Thus, there are 4 observations for each \( Y_i, i = 1, 2 \), and 2 observations for the mixed variable \( D \).

We modified this methodology to construct two instance families of covariance matrices varying in size from \( 120 \times 120 \) to \( 600^2 \times 600^2 \).

1. **Scaled family.** In this instance family the descriptive variables are as follows:

\[ Y_1, Y_2 \sim \text{independently } N(0, \sigma_i^2), \quad D = 0.8 Y_1 - 0.35 Y_2, \]

where \( \sigma_1^2 = 200 \) and \( \sigma_2^2 = 250 \). Each instance of size \( s \) was generated by scaling the number of observations by a positive scalar \( s \) as follows:

\[ X_i = \begin{cases} 
Y_1 + \eta_i, & 1 \leq i \leq 4s, \\
Y_2 + \eta_i, & 4s + 1 \leq i \leq 8s, \\
D + \eta_i, & 8s + 1 \leq i \leq 10s, \\
\eta_i, & 10s + 1 \leq i \leq 12s.
\end{cases} \]

For this family, the dimension of the covariance matrix is \( n = 12s \), and the sparsity variable is \( \kappa = 4s \). The theoretical optimal sparse principal component has loadings on the variables in the set \( \{ X_i : 4s + 3 \leq i \leq 8s \} \), i.e., the variables associated with \( Y_2 \). We choose ten instances each for \( s \in \{ 10, 20, \ldots, 200 \} \cup \{ 300, 400, 500 \} \).

2. **Fixed family.** In this instance family, we fix the number of observations associated with each descriptive variable \( Y_i \) at 4 and those associated with \( D \) at 2, and we scale the number of descriptive variables up by a positive factor \( c \). The variance of the normal random variables was scaled to ensure a dominant component. In particular, we set

\[ Y_i \sim N(0, 4i^2), \quad i = 1, \ldots, c, \quad D = \sum_{i=1}^{c} \frac{1}{\sqrt{c}} Y_i \]

and generated the observations as follows:

\[ X_i = \begin{cases} 
Y_t + \eta_i, & 4(t-1) < i \leq 4t, t = 1, \ldots, c, \\
D + \eta_i, & i = 4t + 1, 4t + 2.
\end{cases} \]

For this family, the size of the covariance matrix is \( n = 4c + 2 \), and the sparsity variable is set to \( \kappa = 4 \). The theoretical optimal sparse principal component has loadings on the variables in the set \( \{ X_i : 4c - 3 \leq i \leq 4c \} \), i.e., the variables associated with \( Y_c \). We chose ten instances each for \( c \in \{ 30, 60, \ldots, 600 \} \cup \{ 900, 1200, 1500 \} \).

We summarize the data generated in Table 2.

In Table 3 (resp., Table 4) the column labeled “mean” reports the CPU seconds (resp., number of iterations) averaged over 10 instances for each problem size, the column labeled “stand. dev.” reports the standard deviation of the runtimes (resp., iteration counts), and the column labeled “max” reports the maximum CPU time (resp., iterations) over the 10 instances. In Figure 2 we display a plot of the runtimes as a function of the problem size $n$. These numerical results support the following observations.

(a) The average number of iterations required to solve instances from the scaled family was relatively small, ranging from 29 to 56. Also, the standard deviation remained fairly consistent, ranging from 11 to 25. The average number of iterations required to solve the fixed family was larger and varied more, ranging between 37 and 134 iterations. The standard deviation varied more as well, ranging from 48 and 256.

(b) The best fit line for the average runtime in real seconds is as follows:

Scaled family : $\log(R) = -5.61 + 2.61 \log(n)$

Fixed family : $\log(R) = -6.16 + 2.88 \log(n)$

Thus, the running time grows as some function which is $O(n^3)$, outperforming the theoretical bound by $\Omega(n)$.

From the results reported in Table 3, it is easy to check that the average runtime per iteration grew at the same rate as the overall runtime. The scaled family had a slightly smaller runtime per iteration growth than the fixed family, which implies that the main bottleneck is the $O(n^3)$ operations required to compute the matrix exponential. The runtime per iteration (and also the overall runtime) should decrease significantly if the shift-invert Lanczos method
is used to compute the matrix exponential. Another possibility is to use a quadratic prox-function for the primal smoothing.

(c) The instances from the fixed family were more difficult when compared to the instances from the scaled family, both in terms of runtime per iteration and iteration growth. The principal difference between the two families was that the cardinality constraint $\kappa$ remained fixed at four for the fixed family, whereas in the scaled family, $\kappa$ grew linearly with the scaling factor $s$.

We compared the performance of our algorithm against the self-dual-minimization code of [27], also called SeDuMi. In general, our algorithm was orders of magnitude faster than SeDuMi [27]. However, with default settings SeDuMi was not able to solve the instances we studied—SeDuMi crashed on instances with covariance matrices larger than $50 \times 50$. Consequently, we do not have SeDuMi runtimes to report. Our runtimes are also significantly superior to the runtimes reported in [7].

Appendix A. Details of our prox-functions.

A.1. The dual prox-function. In order to keep the notation simple, we relabel the slack variable $s_v$ in (49) as $v_{m+1}$.

**Lemma 12.** Let $d_v(v) = \sum_{i=1}^{m+1} v_i \ln(v_i) - \omega v \ln(\omega v/(m+1))$, where $v \in V = \{v: v \geq 0, \sum_{i=1}^{m+1} v_i = \omega v\}$.

1. $d_v$ is strongly convex with convexity parameter $\sigma_v = \frac{1}{\omega v}$ on the interior of $V$.
2. Let

$$v^* = \arg\min_{v \in V} \{\gamma^\top v + \mu_v d_v(v)\}. $$
Then
\[ v_i^* = \frac{\omega_i e^{-\gamma_i / \mu_v}}{\sum_{k=1}^{m+1} e^{-\gamma_k / \mu_v}}, \quad i = 1, \ldots, m + 1. \]

3. \( d_v(\cdot) \geq 0 \) on \( \mathcal{V} \), and \( D_v = \omega_v \log(m + 1) \).

Proof. The Hessian
\[ \nabla^2 d_v(v) = \text{diag}([1/v_1, \ldots, 1/v_{m+1}]) \]
is positive definite on any \( v \in \mathcal{V} \cup \mathbb{R}^{m+1} \). Fix such a \( v \). Then for any \( w \in \mathbb{R}^{m+1} \),
\[ w^T \nabla^2 d_v(v) w = \sum_{i=1}^{m+1} \frac{w_i^2}{v_i}, \]
\[ = \left( \sum_{i=0}^{m} \frac{w_i^2}{v_i} \right) \left( \frac{1}{\omega_v} \sum_{i=1}^{m+1} v_i \right), \]
\[ \geq \frac{1}{\omega_v} \left( \sum_{i=0}^{m} \frac{|w_i|}{\sqrt{v_i} \sqrt{v_i}} \right)^2, \]
\[ = \frac{1}{\omega_v} ||w||^2, \tag{53} \]
where (53) follows from the Cauchy–Schwartz inequality applied to the vectors \( s = [w_1/\sqrt{v_1}, \ldots, w_{m+1}/\sqrt{v_{m+1}}]^T \) and \( s = [\sqrt{v_1}, \ldots, \sqrt{v_{m+1}}]^T \).

Since the objective function of the optimization problem (52) is strongly convex and the Slater condition holds, it follows that the optimum solution is the unique Karush–Kuhn–Tucker point for the problem. The Lagrangian function for the optimization problem (52) is given by
\[ L(v, \beta) = \gamma^T v + \mu_v d_v(v) + \beta \left( \omega_v - \sum_{i=1}^{m+1} v_i \right) + \rho^T v, \]
where \( \beta \) and \( \rho \) are the penalty multipliers. Setting the gradient of the Lagrangian function to zero, we get
\[ 0 = \nabla_v L(v, \beta) = \left[ \begin{array}{c} \gamma_i + \mu_v (1 + \ln(v_i^*)) - \beta \\ \vdots \\ \gamma_{m+1} + \mu_v (1 + \ln(v_{m+1}^*)) - \beta \end{array} \right] \]
or equivalently \( v_i^* = e^{-(\gamma_i / \mu_v)} e^{\beta + \mu_v} \), \( i = 1, \ldots, m + 1. \) Since \( v_i^* > 0 \) for all choices of \( \beta \) and \( \rho \), the complementary slackness condition \( \rho_i v_i^* = 0 \) implies that \( \rho_i = 0 \). Thus, \( v_i^* = e^{-(\gamma_i / \mu_v)} e^{\beta} \), \( i = 1, \ldots, m + 1. \) Since \( \sum_{i=1}^{m+1} v_i^* = \omega_v \), it follows that
\[ e^{\beta} = \sum_{i=1}^{m+1} \frac{\omega_v}{e^{-\gamma_i / \mu_v}}. \]
and the optimal \( v_i^* = \omega_v e^{-\gamma_i / \mu_v} / \sum_{k=1}^{m+1} e^{-\gamma_k / \mu_v}, \quad i = 1, \ldots, m + 1. \)

By setting \( \gamma = 0 \), we see that \( \nu = \arg\min_{v \in \mathcal{V}} d_v(v) = \frac{\omega_v}{m+1} \mathbf{1}, \) and \( d_v(\nu) = 0. \) Thus, it follows that \( d_v(\nu) = d_v(\mathbf{e}) = \omega_v \ln(m + 1). \)

Since \( d_v(v) \) is a convex function and \( \mathcal{V} \) is a simplex, it follows that the optimal value of \( \max_{v \in \mathcal{V}} d_v(v) \) is achieved at an extreme point of \( \mathcal{V} \). The extreme points of \( \mathcal{V} \) are given by \( \omega_v \mathbf{e}_i, \quad i = 1, \ldots, m + 1, \) and at any of these points \( d_v(\omega_v \mathbf{e}_i) = \omega_v \ln(m + 1). \) Thus, \( D_v = \omega_v \ln(m + 1). \) \( \square \)
A.2. The primal prox-function. The primal prox-function in (41) (which is also used in [23]) is

\[ d_x(X) = \sum_{i=1}^{n} \lambda_i(X) \ln(\lambda_i(X)) + s_x \ln(s_x) - \omega_x \ln(\omega_x/(n+1)) \]

for \( X \in \mathcal{X} = \{ X \geq 0 : \text{Tr}(X) \leq \omega_x \} \), and \( s_x = \omega_x - \text{Tr}(X) \). In order to keep the notation simple, we will work with the matrix

\[ \hat{X} = \begin{bmatrix} X & 0^T \\ 0 & s_x \end{bmatrix}. \]

In terms of the new variables the prox-function \( d_x(\hat{X}) = \sum_{i=1}^{\kappa} \lambda_i(\hat{X}) \ln(\lambda_i(\hat{X})) - \omega_x \ln(\omega_x/(n+1)) \). The prox-function \( d_x \) is simply the dual prox-function \( d_v \) evaluated on the eigenvalues of \( \hat{X} \).

**Lemma 13.** Let \( d_x(X) = \sum_{i=1}^{\kappa} \lambda_i(X) \ln(\lambda_i(X)) - \omega_x \ln(\omega_x/(n+1)) \), where \( X \in \mathcal{X} = \{ X \geq 0 : \text{Tr}(X) = \omega_x \} \).

1. \( d_x \) is strongly convex with convexity parameter \( \sigma_v = \frac{1}{\omega_x} \) with respect to the norm \( \|X\|_1 = \sum_{i=1}^{\kappa} |\lambda_i(X)| \) on the interior of \( \mathcal{X} \).

2. Let \( \mu = \frac{1}{\omega_x} \text{Tr}(\hat{X}) \)

\[ (55) \quad X^* = \underset{X \in \mathcal{X}}{\arg\max} \{ \langle \Gamma, X \rangle - \mu x d_x(X) \} = \frac{\omega_x e^{\mu \Gamma}}{\text{Tr}(e^{\mu \Gamma})}. \]

3. Then \( d_x(.) \geq 0 \) on \( \mathcal{X} \) and \( D_x = \omega_x \log(n+1) \).

**Proof.** From results in [3] it follows that \( d_x(X) \) is strongly convex with respect to the \( \ell_1 \)-norm, \( \|X\|_1 = \sum_{i=1}^{\kappa} |\lambda_i(X)| \).

Let \( \lambda \in \mathbb{R}^{n+1} \) such that \( \lambda_1 \geq \lambda_2 \geq \cdots \geq \lambda_{n+1} \geq 0 \) and \( \sum_{i=1}^{n+1} \lambda_i = 1 \) denote the ordered eigenvalues of a matrix \( X \in \mathcal{X} \). Note that the value of the function \( d_x(X) \) is completely determined by the eigenvalues of \( X \). Thus, the eigenvectors of the optimal \( X \) are completely determined by the matrix \( \Gamma \).

Let \( \Gamma = U^T \text{diag}(\gamma) U \) denote the eigendecomposition of the matrix \( \Gamma \), where we let \( \gamma_1 \geq \gamma_2 \geq \cdots \geq \gamma_{n+1} \). Then

\[ \langle \Gamma, X \rangle = \sum_{i=1}^{n+1} \gamma_i u_i^T X u_i \leq \sum_{i=1}^{n+1} \gamma_i \lambda_i, \]

where equality holds only if \( u_i \), \( i = 1, \ldots, k \), are the eigenvectors corresponding to the \( k \) largest eigenvalues of \( X \). It follows that for a fixed \( \lambda \) the optimal set of eigenvectors for the matrix \( X \) is given by the eigenvectors of \( \Gamma \).

Now our problem reduces to computing the optimal set of eigenvalues \( \lambda \). From Lemma 12 it follows that the optimal \( \lambda^* \) is given by

\[ \lambda^*_i = \frac{e^{\gamma_i/\mu_x}}{\sum_{k=1}^{n+1} e^{\gamma_k/\mu_x}}, \quad i = 1, \ldots, n+1. \]

Thus,

\[ X^* = \frac{U^T \text{diag}([e^{\gamma_1/\mu_x}, \ldots, e^{\gamma_{n+1}/\mu_x}]) U}{\text{Tr} (U^T \text{diag}([e^{\gamma_1/\mu_x}, \ldots, e^{\gamma_{n+1}/\mu_x}]) U)} = \frac{e^{1/\mu \Gamma}}{\text{Tr}(e^{1/\mu \Gamma})}. \]
Setting $\Gamma = 0$, it follows that $\arg\min_{X \in \mathcal{X}} d_x(X) = \frac{\omega_x}{n+1}I$. Consequently, for all $X \in \mathcal{X}$ we have that $d_x(X) \geq d_x(\omega_x/(n+1)I) = 0$.

Since $d_x(X)$ is a convex function on the eigenvalues of $X \in \mathcal{X}$ which lie in a simplex, it follows that the optimal value of $\max_{X \in \mathcal{X}} d_x(X)$ is achieved at an extreme point of $\mathcal{X}$. The extreme points of $\mathcal{X}$ are given by $\omega_x uu^\top$, where $u \in \mathbb{R}^{n+1}$ with $\|u\| = 1$ and at any of these point $d_x(\omega_x uu^\top) = \omega_x \ln(n+1)$. Thus, $D_x = \omega_x \ln(n+1)$.

**Appendix B. Matrix exponential via Lanczos iterations.** The most expensive step in using the Nesterov procedure to solve the Lagrangian relaxation of the packing SDP is computing the optimal

$$
X^* = \arg\max_{X \in \mathcal{X}} \left\{ (\Gamma, X) - \mu_x d_x(X) \right\} = \frac{\omega_x e^{\frac{\omega_x}{n+1} \Gamma}}{1 + \text{Tr} \left( e^{\frac{\omega_x}{n+1} \Gamma} \right)},
$$

where $e^{\frac{\omega_x}{n+1} \Gamma}$ denotes the matrix exponential for a matrix $\Gamma \in S^n$ scaled by a positive constant $\mu_x \in \mathbb{R}_{++}$. Let $\Gamma = V \text{diag}(\gamma) V^\top$, where $\gamma$ denotes the vector of eigenvalues of $\Gamma$ and $V$ denotes the matrix with rows equal to the corresponding eigenvectors of $\Gamma$. Then

$$
X^* = \frac{V \text{diag}(e^{\frac{\omega_x}{n+1} \Gamma}) V^\top}{1 + \sum_{i=1}^{n} e^{\frac{\omega_x}{n+1} \gamma_i}},
$$

where $\text{diag}(e^{\frac{\omega_x}{n+1} \gamma})$ denotes a diagonal matrix with the $i$th entry equal to $e^{\frac{\omega_x}{n+1} \gamma_i}$. Thus, we can compute $X^*$ by first computing the eigendecomposition of $\Gamma$. However, the complexity of this procedure is $O(n^3)$.

Matrix exponentials appear in solving discrete approximations of elliptic partial differential equations. Therefore, there has been a lot of interest in the applied numerical mathematics community to efficiently compute approximations to a matrix exponential. Currently, the best known techniques for efficiently computing the matrix exponential rely on using the Lanczos method to computing the basis of the Krylov subspaces associated with the matrix $\Gamma$ [10, 13] or $(I + \theta \Gamma)^{-1}$ [31] for an appropriately chosen $\theta$. Theorem 3.3 of [31] indicates that $O(\log^2(\epsilon^{-1})$ Lanczos iterations are required to approximate the matrix-vector product $\exp(\Gamma)v$ for any $v \in \mathbb{R}^n$. Setting $v = e_i$, $i = 1, \ldots, n$, results in an overall complexity of $O(nr \log^3(\epsilon^{-1}))$, where $r$ denotes the number of nonzero elements in $\Gamma$. Thus, we have the following corollary.

**Corollary 14.** The complexity of computing $\exp(\Gamma/\mu)$ via the Shift-Invert-Lanczos procedure proposed in [31] is $O(nr \log^3(\epsilon^{-1}))$, where $r$ denotes the number of nonzero terms in the matrix $\Gamma$. Also, computing $\exp(\Gamma/\mu)v$ for any $v \in \mathbb{R}^n$ requires $O(r \log^3(\epsilon^{-1}))$ time.

In practice, Corollary 14 is of limited value for calculating the full matrix exponential. However, as noted in [8], a partial matrix exponential can be used to approximate the gradient successfully.

**Appendix C. The sparse PCA packing SDP.**

**C.1. Sparse PCA dual prox-function.**

**Lemma 15.** Let

$$
d_y(v, Y) = \frac{1}{2} \|v\|^2 + \frac{1}{2} \sum_{i,j} |Y_{ij}|^2
$$

and $\mathcal{Y} = \{ (v, Y) : 0 \leq v \leq 1, |Y_{ij}| \leq v \}$.  

function of the quadratic program (58) is given by

\[
(v^*, Y^*) = \arg \min_{(v,Y) \in \mathcal{Y}} \{(X,Y) + \ell v + \mu_y d_y(v,Y)\}
\]

Let \(\{ \beta_i : t = 1, \ldots, \tau \}\) denote the distinct values in the set \(\{ \mu_y^{-1} |x_{ij}| : 0 < \mu_y^{-1} |x_{ij}| < 1\}\) sorted in increasing order. Set \(\beta_0 = 0\). For \(k = 0, \ldots, \tau - 1\), define

\[
\alpha_k = \frac{-\ell + \mu_y \sum_{(ij : |x_{ij}| > \mu_y \beta_k)} |x_{ij}|}{\mu_y (1 + |\{(ij : |x_{ij}| > \beta_k)\}|)}.
\]

Then

\[
Y^*_{ij} = -\text{sgn}(X_{ij}) \cdot \min \left\{ \frac{|x_{ij}|}{\mu_y}, v^* \right\},
\]

(57)

\[
v^* = \begin{cases} 0, & \ell + \sum_{ij} |x_{ij}| \geq 0, \\ 1, & \ell + \mu_y + \sum_{ij} \max\{0, |x_{ij}| - \mu_y\} \leq 0,
\end{cases}
\]

\[
\alpha_k \quad \text{for some } k \in \{0, \ldots, \tau - 1\}.
\]

3. \((v^*, Y^*)\) can be computed in \(O(n^2 \ln(n))\) operations.

**Proof.** The strong convexity of \(d_y\) with \(\sigma_y = 1\) follows immediately from the fact that \(\nabla^2 d_y(v, Y) = I_{n^2+1}\).

From the definition of \(d_y\) it follows that

\[
\min_{(v,Y) \in \mathcal{Y}} \{(X,Y) + \ell v + \mu_y d_y(v,Y)\}
\]

(58) = \min \left\{ \ell v + \sum_{i,j} x_{ij} y_{ij} + \frac{\mu_y}{2} \left( v^2 + \sum_{i,j} y_{ij}^2 \right) : 0 \leq v \leq 1, -v \leq y_{ij} \leq v \right\}.

Since \(d_y\) is strongly convex, it follows that (58) has a unique solution. The Lagrangian function of the quadratic program (58) is given by

\[
L(v, Y, p, q, r, s) = \ell v + \sum_{i,j} x_{ij} y_{ij} + \frac{\mu_y}{2} \left( v^2 + \sum_{i,j} y_{ij}^2 \right) + p(v - 1) - qv + \sum_{i,j} \left( r_{ij} (y_{ij} - v) - s_{ij} (y_{ij} + v) \right),
\]

where \(p, q, r_{ij}, s_{ij} \geq 0\). Then \((v^*, Y^*)\) is optimal for (58) if and only if \((v^*, Y^*)\) is feasible and there exist multipliers \(p^*, q^*, r_{ij}^*, s_{ij}^* \geq 0\) such that

\[
\nabla Y_{ij} L(v, Y) \big|_{(v^*, Y^*)} = X_{ij} + \mu_y y_{ij}^* + r_{ij}^* - s_{ij}^* = 0,
\]

(59)

\[
\nabla_v L(v, Y) \big|_{(v^*, Y^*)} = \ell + \mu_y v^* + p^* - q^* - \sum_{i,j} (r_{ij}^* + s_{ij}^*) = 0,
\]

and the complementary slackness conditions

\[
p^*(1 - v^*) = q^* v^* = r_{ij}^*(v^* - Y_{ij}^*) = s_{ij}^*(Y_{ij}^* + v^*) = 0
\]
hold. From the gradient condition for \( Y_{ij}^* \) in (59) and the complementary slackness conditions for \( r_{ij}^* \) and \( s_{ij}^* \) it follows that

\[
Y_{ij}^* = -\text{sgn}(X_{ij}) \cdot \min \left\{ \frac{|X_{ij}|}{\mu_y}, v^* \right\},
\]

\[
r_{ij}^* = (X_{ij} - \mu_y v^*)^+, \\
s_{ij}^* = (-\mu_y v^* - X_{ij})^+.
\]

Thus, we have

\[
(60)
\]

Using the gradient condition for \( v^* \) in (59), we have that

\[
f(v^*) \triangleq \ell + \mu_y v^* - \sum_{ij} (r_{ij}^* - s_{ij}^*) = \ell + \mu_y v^* - \sum_{ij} \max\{0, |X_{ij}| - \mu_y v^*\} = q^* - p^*.
\]

Note that \( f(v^*) \) is the gradient of the objective with respect to \( v^* \). We now compute the optimal \( v^* \) using case analysis.

(i) \( f(0) = \ell - \sum_{ij} |X_{ij}| \geq 0 \). Set \( v^* = 0, p^* = 0, \) and \( q^* = f(0) \geq 0 \). Then \((v^*, p^*, q^*)\) satisfy the gradient condition and the complementary slackness conditions.

(ii) \( f(1) = \ell + \mu_y - \sum_{ij} \max\{0, |X_{ij}| - \mu_y\} \leq 0 \). Set \( v^* = 1, p^* = -f(1) \geq 0, \) and \( q^* = 0 \). Then \((v^*, p^*, q^*)\) satisfy the gradient condition and the complementary slackness conditions.

(iii) \( f(1) > 0 > f(0) \). Since \( f(v^*) \) is a continuous function of \( v^* \), it follows that there exists \( v^* \in (0, 1) \) with \( f(v^*) = 0 \). Since \( f(v^*) \) is piecewise linear, we can compute \( v^* \) by sorting \( \{ |X_{ij}| : 1 \leq i, j \leq n \} \).

Let \( \{ \beta_k : t = 1, \ldots, \tau \} \) denote the distinct values in the set \( \{ \mu_y^{-1}|X_{ij}| : 0 < \mu_y^{-1}|X_{ij}| < 1 \} \) sorted in increasing order. Let \( \beta_0 = 0 \). Since \( f(\alpha) = \ell + \mu_y \alpha - \sum_{i,j:|X_{ij}| > \mu_y \beta_k} \mu_y (|X_{ij}| - \alpha) \), for \( \alpha \in (\beta_k, \beta_k+1], k = 0, \ldots, \tau - 1 \), there exists \( v^* \in (\beta_k, \beta_{k+1}] \) with \( f(v^*) = 0 \) if and only if

\[
v^* = \alpha_k \triangleq \frac{-\ell + \mu_y \sum_{i,j:|X_{ij}| > \mu_y \beta_k} |X_{ij}|}{\mu_y (1 + \{|i,j : |X_{ij}| > \beta_k\})}.
\]

The computational cost of computing \( v^* \) is dominated by the cost of sorting \( \{ \mu_y^{-1}|X_{ij}| \} \) and can, therefore, be computed in \( O(n^2 \ln(n)) \) time.

C.2. Rounding sparse PCA solutions. Recall that we assume \( \kappa > 1 \) since the sparse PCA problem reduces to \( \arg \max \{ C_{ii} : 1 \leq i \leq n \} \) when \( \kappa = 1 \).

Lemma 16. Suppose \( \kappa > 1 \). Let \( \overline{X} \) denote an \( \epsilon \)-saddle-point for the sparse PCA saddle-point problem (51). Let \( \overline{W} = \text{diag}(\overline{X}) \) and \( \overline{Z} = \overline{X} - \overline{W} \). Set

\[
(62)
\]

where \( \gamma = \min \{ 1, \frac{1-g(\overline{X})}{g(\overline{Z})} \} \). Then \( \hat{X} \) is a feasible, \( \left( \frac{\kappa \epsilon}{\kappa - 1} \right) \)-optimal solution to the sparse PCA packing SDP (16).

Proof. The packing constraint in the sparse PCA problem is given by

\[
g(X) = \frac{1}{\kappa} \sum_{i,j} |X_{ij}|.
\]
Let $A = D + E$, where $D$ and $E$ are disjoint components of $A$, i.e., $D_{ij}E_{ij} = 0$ for all $1 \leq i,j \leq n$. For example, $D = \text{diag}(A)$ and $E = A - D$ are disjoint components of $A$. Then

$$g(A) = g(D) + g(E).$$

Since $\text{Tr}(X) = 1$ and $W = \text{diag}(X) \succeq 0$, it follows that $g(W) = \frac{1}{\kappa} \text{Tr}(W) = \frac{1}{\kappa} < 1$; i.e., $W$ is strictly feasible for the sparse PCA packing SDP (16).

We now show the theorem by case analysis depending on the value of $Z$.

(a) $\langle C, Z \rangle \leq 0$. Then $\langle C, W \rangle = \langle C, \bar{X} \rangle - \langle C, Z \rangle \geq \langle C, \bar{X} \rangle$. Since $\bar{W}$ is feasible for (16), it follows that $\bar{W}$ is an $\epsilon$-optimal solution for the sparse PCA packing SDP (16).

(b) $\langle C, Z \rangle > 0$. Note that

$$\gamma = \max \{ \alpha : g(W + \alpha Z) \leq 1, \alpha \leq 1 \}.$$

Consider the following two cases:

(i) $\gamma = 1$. In this case $g(\bar{X}) \leq 1$. Thus, $\bar{X}$ is feasible for the sparse PCA SDP.

The $\epsilon$-optimality follows as in the proof of Theorem 3.

(ii) $\gamma < 1$. Then (63) implies

$$g(\hat{X}) = g(\bar{W} + \gamma Z) = g(\bar{W}) + \gamma g(\bar{Z}) = g(\bar{W}) + \frac{1 - g(\bar{W})}{g(\bar{Z})} \cdot g(\bar{Z}) = 1.$$

Also,

$$\hat{X} = \bar{W} + \gamma Z = \bar{W} + \gamma (X - \bar{W}) = (1 - \gamma) \bar{W} + \gamma X \succeq 0.$$

Thus, $\bar{X}$ is feasible for (16).

Let $\bar{d} = g(\bar{X})$. Since $\gamma < 1$, it follows that $\bar{X}$ is infeasible, i.e., $\bar{d} = g(\bar{X}) > 1$.

Since $g(\bar{W}) = \frac{1}{\kappa}$ and $g(\bar{Z}) = g(\bar{X}) - g(\bar{W}) = \bar{d} - \frac{1}{\kappa}$, it follows that

$$\gamma = \frac{\kappa - 1}{\kappa \bar{d} - 1} = \frac{1}{1 + \frac{\kappa - 1}{\kappa \bar{d} - 1}} \geq 1 - \frac{\kappa}{\kappa - 1} \frac{1}{\bar{d} - 1}.$$

Thus,

$$\langle C, \bar{X} \rangle = \langle C, \bar{W} \rangle + \gamma \langle C, Z \rangle$$

$$\geq \langle C, \bar{W} \rangle + (1 - \frac{\kappa}{\kappa - 1} (\bar{d} - 1)) \langle C, Z \rangle$$

$$\geq \langle C, \bar{X} \rangle - \frac{\kappa}{\kappa - 1} (\bar{d} - 1) \langle C, Z \rangle$$

$$\geq \langle C, X \rangle - \frac{\kappa}{\kappa - 1} (\bar{d} - 1) \langle C, X \rangle,$$

where (64) follows from same argument as in Theorem 3 and (65) follows from that fact that $\langle C, \bar{W} \rangle + \langle C, Z \rangle = \langle C, \bar{X} \rangle$ and $C, \bar{W} \succeq 0$ (so $\langle C, \bar{W} \rangle \geq 0$). Then (28), (29), and (30) from the proof of Theorem 3 imply that $\langle C, \bar{X} \rangle \geq \rho^* - \frac{\kappa}{\kappa - 1} \epsilon$. 
Thus, we have that $\mathbf{X}$ is a feasible, $\frac{1}{\kappa+1}$-optimal solution to (4).

The following lemma establishes the correctness of a stopping criterion used in our sparse PCA code.

**Lemma 17.** Let $(\nu(k), Y(k))$, $k \geq 0$, denote the sequence dual iterates generated by the Nesterov algorithm displayed in Figure 1 applied to the sparse PCA problem. Then the primal iterates

\[(66) \quad X^{(k)} = \arg \max_{X \in \mathcal{X}} \left\{ \langle C, X \rangle + \nu(k) - \frac{1}{\kappa} \langle Y(k), X \rangle - \mu_x d_x(X) \right\}.
\]

Let $X^{(t)} = \sum_{k=0}^{t} \frac{2(k+1)}{(t+1)(t+2)} X^{(k)}$ denote the primal solution returned by the Nesterov algorithm if it were to be terminated at iteration $t$. Let $W^{(t)} = \text{diag}(X^{(t)})$ and $Z^{(t)} = X^{(t)} - W^{(t)}$. Define

\[\hat{X}^{(t)} = \begin{cases} \frac{W^{(t)}}{t}, & \langle C, Z^{(t)} \rangle \leq 0, \\ \frac{W^{(t)}}{t} + \gamma^{(t)} Z^{(t)}, & \text{otherwise}, \end{cases}\]

where $\gamma^{(t)} = \min \{ 1, \frac{1 - g(W^{(t)})}{g(Z^{(t)})} \}$.

Suppose $X^{(t)}$ is $\delta$-feasible for the packing constraint, i.e., $g(X^{(t)}) \leq 1 + \delta$. Then

\[\langle C, X^{(t)} \rangle \geq \left( 1 - \frac{\kappa}{\kappa-1} \delta \right) \left( \langle C, X^\ast \rangle - \frac{\epsilon}{2} - \sigma^{(t)} \right),\]

where

\[\sigma^{(t)} = \sum_{k=0}^{t} \frac{2(k+1)}{(t+1)(t+2)} \left( \nu(k) - \frac{1}{\kappa} \langle Y(k), X \rangle \right)\]

denotes the average infeasibility of the iterates $\{X^{(k)}\}$ and $X^\ast$ denotes the optimal solution to sparse PCA packing SDP (16).

**Proof.** From (66) it follows that

\[\langle C, X^{(k)} \rangle - \frac{1}{\kappa} \langle Y(k), X^{(k)} \rangle \geq \langle C, X^\ast \rangle - \frac{1}{\kappa} \langle Y(k), X^\ast \rangle - \mu_x (d_x(X^\ast) - d_x(X^{(k)})).\]

Since $X^\ast$ is feasible, i.e., $\|X^\ast\|_1 = \max_{\{Y: \|Y\|_1 \leq 1\}} \langle Y, X^\ast \rangle \leq 1$, it follows that $\nu(k) - \frac{1}{\kappa} \langle Y(k), X \rangle \geq 0$, and

\[\langle C, X^{(t)} \rangle \geq \langle C, X^\ast \rangle - \left( \nu(k) - \frac{1}{\kappa} \langle Y(k), X^{(k)} \rangle \right) - \mu_x (d_x(X^\ast) - d_x(X^{(k)})).\]

Since $\mu_x = \frac{1}{2D_x}$ and $d_x(X^\ast) - d_x(X^{(k)}) \leq D_x$, it follows that

\[\langle C, X^{(t)} \rangle \geq \langle C, X^\ast \rangle - \left( \frac{\mu(k)}{\kappa} - \frac{1}{\kappa} \langle Y(k), X^{(k)} \rangle \right) - \frac{\epsilon}{2}.
\]

Hence,

\[(67) \quad \langle C, X^{(t)} \rangle \geq \langle C, X^\ast \rangle - \sigma^{(t)} - \frac{\epsilon}{2}.
\]

Next, consider the following two cases:
(a) \( \langle C, Z^{(t)} \rangle < 0 \). Since (63) implies that \( \langle C, X^{(t)} \rangle = \langle C, W^{(t)} \rangle + \langle C, Z^{(t)} \rangle = \langle C, X^{(t)} \rangle + \langle C, Z^{(t)} \rangle \), it follows that \( \langle C, X^{(t)} \rangle > \langle C, X^{(t)} \rangle \). Thus, the result follows.

(b) \( \langle C, Z^{(t)} \rangle \geq 0 \). In this case, an argument similar to that employed in the proof of Lemma 16 establishes that

\[
\langle C, X^{(t)} \rangle \geq \left( 1 - \frac{\kappa}{\kappa - 1} \right) \max \{ g(X^{(t)}) - 1, 0 \} \langle C, X^{(t)} \rangle.
\]

The result follows from the fact that \( g(X^{(t)}) - 1 \leq \delta \). \( \square \)

Acknowledgments. We thank the referees and associate editor for their helpful comments. Also, we thank Satyen Kale and Michael Lewis for useful discussions and David Steurer for pointing out the reformulation of the MAXCUT problem. We also thank Tom Crockett for his help setting up the computational experiments. Computational facilities at the College of William and Mary were provided with the assistance of the National Science Foundation, the Virginia Port Authority, Sun Microsystems, and Virginia’s Commonwealth Technology Research Fund.
